DISEASES OF CHILDREN.

BY THE SAME AUTHOR.

- HEADACHES: Their Causes, Nature, and Treatment.

 Third Edition. Revised and Enlarged. 12mo. Cloth. Price,
 \$2.00.
- "Dr. Day brings to bear upon his subject a large amount of experience and medical knowledge, and makes many therapeutical suggestions of extreme value."—Lancet.
- "The rapidity with which this book has reached a third edition shows how well it has been appreciated by the profession,"—Practitioner.
- "It will always be a book of reference for the practitioner."—New York Medical Journal.
- "The extensive demand for a really good treatise on the subject is shown by the publication of the third edition of Dr. Day's work,"—Edinburgh Medical Journal.

DISEASES OF CHILDREN;

A

PRACTICAL AND SYSTEMATIC WORK

FOR

PRACTITIONERS AND STUDENTS.

BY

WILLIAM HENRY DAY, M.D.,

AUTHOR OF HEADACHES; THEIR CAUSE, NATURE, AND TREATMENT,
MEMBER OF THE ROYAL COLLEGE OF PHYSICIANS OF LONDON,
PHYSICIAN TO THE SAMARITAN HOSPITAL FOR WOMEN AND CHILDREN.

SECOND EDITION.

REWRITTEN AND MUCH ENLARGED

PHILADELPHIA:
PRESLEY BLAKISTON,
No. 1012 WALNUT STREET.
1881.

TO MY COLLEAGUES,

THE PHYSICIANS AND SURGEONS

OF THE

SAMARITAN HOSPITAL,

Ehle Bloch in Debirateb.

THEFT

EVERY SENTIMENT OF RESPECT AND ESTREM,

W

THE AUTHOR.

PREFACE.

Thus volume is the outcome of private and hospital practice, extending over a lengthened period. My aim has been to make the work useful, and to rely on clinical experience rather than on theories; which, even when proved, cannot always be brought to bear on points of practical interest.

I entertain the hope that the following pages may prove useful both to the student and to the practitioner. To assist the student, I have classified each disease and its varieties, after the method sanctioned by modern pathologists. To help the practitioner, I have carefully placed a descriptive heading before each chapter, to enable him to obtain readily the information he requires:

In arranging the list of prescriptions, concentration has been my aim. Certain broad principles are kept in view, as regards dose and combination, but the details can be varied at the discretion of the practitioner, according to the peculiarities of each case as met with in practice. I have invariably prescribed remedies in safe doses. Some medicines will be taken by children in large proportions and a cure effected when small doses fail. Thus belladonna may cure incontinence of urine, and relieve whooping-cough, when its physical effects are fully produced. Arsenic will cure chosen in large doses, whilst it will frequently fail in small doses. Opium requires to be given with caution. Calonel, iron, ipecacuanha, and free purgatives are well borne by children, while strychnia and prussic acid require care in exhibition.

I have to thank my colleagues at the Samaritan Hospital for the opportunities they have given me of watching interesting cases

VIII PREPACE.

under their care, and of giving me many valuable hints. I have especially to thank Mr. Alban Doran for the assistance he has rendered me in the chapters on Insugination and Intussusception, and on other questions of surgical interest.

My warmest thanks are due to Dr. Milner Fothergill for much information and suggestion.

I have laid myself under great obligation to the writers of standard works, and if I have failed anywhere to acknowledge the debt, the omission has been purely accidental and unintentional.

To the Transactions of the Royal Medical and Chaurgical Society, of the Pathological Society, and of the Clinical Society, as well as to the works of Jones and Sieveking and Wilks and Moxon, I am greatly indebted.

to Marchenine Square; April, 1867.

ERRATA AND ADDENDUM.

Ox page 365, second line from bottom, for "Aquam ad 55" rend "Aquam ad 555."

On page 379, second line from bettern, for "Aquam ad" read "aque an."

On page 206, at bottom, add:

Typhlitic and Perityphlitis.—This disease consists in influmnation of the routs of the execum, and of the tissues above and around it. It may occur without apparent cause, or follow diarrhox or constipation. Blows on the abdomen, exposure to damp and cold, impacted frees, or foreign bodies in the execum may induce it.

The symptoms are pain and tenderness over the right bline fosse, collicky pains in the abdomen, verniting, constitution or distribuse, and febrile disturbance. The patient lies on his back, or right side, with his legs drawn up to relax the abdominal muscles.

The progress is generally favorable unless the disease leads to perforation of the careum and peritonitis. If alseess form, it may open into the bowel or externally through the abdominal wall, the chance of recovery being greater in the former than in the latter.

The disposair consists in sudden localized pain and tenderness in the right illuc fossa, with more or less swelling, vamiting, and constipation. It may be mistaken for hip-discase* or avaritis in young girls who have begun to menstructe, or to the passage of a renal calculus.†

Trentsent.—If pain and tenderness are acute, it will be advisable to apply three or four leeches over the casum, followed by marm and light positions. Opium to refleve pain in small closes by the mouth, or what is preferable, a few drops of hudanum thrown into the rectum. When the pain is refleved, enemata may be used, or even a mild launtive, if there is no vomiting, but the greatest care is necessary in the use of apericuts.

DISEASES OF CHILDREN.

CHAPTER L

INTRODUCTORY REMARKS.

The study of children's disease. Their special characters and permission. Monogeneral charing proach and discipances. Importance of actualing to the constitutional rather than to the food plate. Constitutional and hereditary disease.

Tun diseases of children have a claim to be considered separately and specially. It is before mental training has worked its influence, and the body has undergone the wear and tear of adult life, that we are able to study disease in its most natural form. An opportunity is presented to us of seeing disease, as it were, unrestrained and free, running its course in a tender frame, keenly sensitive to exultation and depression, without the complications and the thousand collateral circumstances which determine the form and character of the disease which is to assail it in subsequent life. All practitioners of medicine will admit that the discases of children should be regarded in a distinct light from like diseases of adults, where too frequently disease acts upon shattered organs and worn out tissues. The remarkable peculiarities which disease assumes in children, the coarse it follows, and the rapid transition from a state of danger to recovery, make this study very important.

Often obscure and difficult of detection, these diseases quickly attain force and intensity, and run on uncontrolled by any measures within our reach. It may be they have slumbered for a variable time in the system, occasioning little, if any disturbance to the general health that could be looked upon as positively foreboding evil to come; or it may be, from causes not readily discoverable. they have a sudden and florer origin. Now and then, after lasting weeks and months together, defying medicine and the highest medical skill, they take a turn in the right direction. Each stage of them is characterized by graver symptoms till a turning-point is reached, and then convalencence sets in slowly and steadily.

A life of physical activity when the renovation of the tissues is most vigorously proceeding makes great calls on the digestive functions, and these again, for the maintenance of their integrity, depend on sleep and repose when marriness acts in. Excessive mental exertion interferes with the growth of the body. The two cannot be actively carried on with impunity at the same time; the one is peculiar to childhood, the other comes naturally with the approach of maturity, and increases with the love of sedentary liabits. When the organic processes are most active they are most easily upset, or hindered in their course, and in this respect alone they differ as much from similar functions in the adult as a thriving shrub does from a full-grown tree.

The children of the present day are reared differently, taught differently, and fed differently from those of half a contary ago, and, as a consequence, the power of disease is greatly modified by such changes. These are very important considerations, and must be borne in mind if we would successfully lay smooth this uneven field of medical inquiry, for I think fault may often be ascribed to us in not adequately estimating the slifference of power between similar diseases in the young child and the adult. It is necessary, then, that the discuss of early life receive a most attentive consideration, for if overlooked, or ill understood, the weeks of mischief are allowed to take deep root, and a degenerate maturity in encouraged. A large number of the children of the poor in London grow up to be tuberculous, and ultimately die of pulmonary phthisis, from disregard of their early illnesses on the part of their parents. Small children, imperfacilly recovered from the eruntive fevers, are allowed to run about in the streets almost before the rush has disaggeured; and the lung affection, which so constantly attends measles, is permitted to go on without any treatment at all. Supporating cervical glands, otorrhoa ending in cerebral disease, dropsy, ophthalmia, etc., all follow in the rear of neglect and starvation. The functions of childhood are remarkable for change, development, and activity; the skin is sensitive to all external influences, diarrhus and vomiting are easily provoked, and the neryours system is very impressible. Hence an amount of cold or heat which would not affect a grown-up person would be fatal to a young child, for in proportion to the rapid changes which are going on there is a proportionate degree of risk. It is no easy task to adjust the balance and to keep it steadily equipoised. Distorler in one part is enough to disturb the whole unchinery, and elight mischief having been set up in an unimportant part may rapidly extend its influence to another distant and vital part.

We have much to learn then, during the period of growth, change, and development. In a great measure children must be managed according to the strength with which they enter into the world. Some are born weak and fragile, and require the most delicate attentions to rear them through this stage. If the same measures are adopted as with stronger children they would either die, or grow up miserably wretebed or unhealthy. No astonishment can be awakened at this if we consider for a moment the life many mothers lead during the trying period of pregnancy. Late hours lead to fatigue, to excitement, and to stimulating and improper diet, which are sure means of causing them to bear an unlealthy offspring. In London and other large cities these remarks are especially applicable. The calm quiet of country life, with regular and abstenders halfits, alone conduces to a natural and tranquil state of mind and body. All this leads to sound and vigorous health in the mother, and as surely to health in the children she bears.

My colleague, Dr. Percy Boulton, has devoted much time and attention to the subject of physical development in children. What Professor Bowelitch, of Boston, has done for Americans, Quetelet for Belgians, and Charles Roberts for English factory children, Dr. Boulton has done for well-to-do English children. The physical averages of factory children are as poor a standard of measurement as their mental averages are a criterion of brain capacity. It seems unnecessary to explain that sypholis, strums, and drink on the one hand; bad food, clothing, housing, and premature excessive bedily labor on the other; tend to stunt the growth of the working classes. An average of the weight and height of factory children is no standard for those more favorably situated in life.

Dr. Boulton has arrived at the following very valuable conclu-

"Healthy children grow at the following rate per annum-

Slow growing.	-	4	4		-	100	2	judice a year.
Attimos								
Past amedian	-3.			-	-	- 1	3	

A child that grows 2 inches a year will be a short adult, 25 inches a medium, and 3 inches a tall adult. Weight should increase regularly with height, and there is no more certain forerunner of disease or unhealthy development than discrepancy in the weight for height ratio. Growth should proceed regularly and evenly, not by fits and starts. Delicate children grow most irregularly. Illness in a great measure checks their development, during which time they lose ground that either is never made up, or only by a bound which sadly taxes the strength."

It is most important that we should have some standard to go by, and this is supplied us in the table of averages which Dr. Boulton has drawn up as the result of very numerous observations of his own amongst the children of healthy well-to-do people. He particularly mentions that his endeavor has been to exclude all dwarfs, giants, and evidently diseased and unbealthy children, which so seriously alter the averages of other observers, and belières that he has thus prepared a scale which may be regarded as a standard for children brought up under favorable conditions.

^{*} Some Anthropometrical Observations, Harrelan Society, Manch, 1860.

The first year of Infant life is especially perilous from defective nutrition and want of proper care." We are assured of this from the fact that the mertality is so much greater among the children of the poor than among those of the rich; in the manufacturing districts of the north, and in overcrowded dwellings, than in rural districts, where the mothers go to field work, and where three or four families are not compelled to reside in one small house. It is a mystery that children can be reared at all in some of our great cities and towns, on account of the impurity of the air they breathe, and the impuritary condition of the hovels they inhabit. Better accommodation must be provided for the poor if we would lessen the waste of infant life and the spread of symotic diseases—a spread accelerated, no doubt, in these days by the rapid intercourse between one country and another.

Those accustomed to children will observe signs and symptoms about them of great weight and significance, which would pass unnoticed by others not possessing this experience. They detect the coming storm, and avert it by simple and appropriate treatment; and so a formidable disease may sometimes be annihilated by good judgment and forethought. There are few discuses occurring in later life that require so much suggesty to detect as the various disorders and ailments of young shildren, or so much discrimination, tact, and judgment in the successful management of them. I have elsewhere stated that constitutional symptoms always demand a large share of attention, and that we have often erred when we have trusted too exclusively to physical and local signs. At all ages and in both sexes, it is my belief that we are never likely to he so successful in controlling disease as when we mainly direct our treatment to the constitutional state. † This does not leaply carelessness of, or indifference to, physical signs. In children the constitutional state should never be forgotten, for many a sound practitioner has lost his little patient, whilst watching the pulse

^{*} It is stated on the anthority of M. Koloen, of Belgium, that the nortality for this period of life in the principal possesses of Europe is as follows: * Our of 1000 children, there die in Seedam 103, in Demonst 136, in Seedam 156, in England 170, in Belgium 188, in Holland 213, in France 256, in Precia 220, in Spain 228, in Switzerland 252, in Indy 254, in America 303, in Bessia 311, and in Buraria 372.*—Bratch Modecof Januari, January 25th, 1877, p. 113.

[†] Fide a paper by the author On the Relative Value of Symptoms in the Dispussion and Treatment of Discout. Transactions of the St. And. Med. Good Association, vol. ii, p. 78, 1889.

closely and listening with care to the respiration, when he might have saved life by leaving these symptoms to take care of themselves and looking to the general state as the sure index of danger, Neither the pulse, the skin, nor any light which assemblation and percussion affect, are such valuable signs of disease in children as they are inadults. Constitutional diseases are the consequences of impairment to the processes of natrition and secretion. In children they are more frequently hereditary than acquired. A child is born with a predisposition to some particular disease, as tubercle, cancer, gout, etc.; but if the life it leads is conducive to sound health, the morbid tendency may never show itself. And this may afford an explanation of a constitutional and hereditary disease skipping one generation and appearing in the next."

When the general and constitutional signs of disease are well established, they are sometimes cut short with the same suddenness with which they attained their severity. But when the physical signs of disease are also well developed, as in some cases of continued fever, bronchitis, and postmuonia, our prognosis becomes far more serious, and a tendency to sudden prostration, and even fatal collapse may steal on in a few hours.

^{* &}quot;The health of an individual depends not merely upon existing, but also on order codest causes. Part of his licable is transmitted from his ascentary, and may be a more survival of largionic conditions which have been estimated. Part of our health also depends upon the external conditions of our ophringing when young, and part also on the influence, physical and moral, is which as use exposed all through our lives. As there is no believedual who can be said to have all his organic functions in the reast profest action, so there is no community that can be considered in a perfectly healthy state, for the personal health depends upon all the movements of the private health of the indicationly. The health of a nation, physiologically considered, stands closely in estation to that of up individual. The restrictes and health of up individual depend upon the well-adjusted balance of the supply and waste of the particles which company the body. These particles of the budy, all through the life of man, are measurably dying and are being enclaced by new particles continually springing into life. Every organ is then makerpoint, through its justicies, a continued and rapid alternation of Scott and life. As the winds body is to one of them particles so is the whole body. political a nation to the individuals of which it is composed. The death of we individeal is a mate is strictly analogous to the death of a particle is a single men, and the bien, of an individual in a state is the assingue of the sensiting of a new living parties into the lede of a man. When an individual becomes discused, there is not a want of halance between the waste and empty of his organi-or rather of the underlying procedures which is incoveredy changing from life to death. When the water of the utilities a particles it greater than the power of netteration, vincene attacks the indiridual "- Address of Dr. Lyon Playfair, On Sanitary Referes, delivered before the Social Science Congress at Ginsgow, October 3d, 1974.

We cannot, in many complaints, so easily determine the extent. and degree of local mischief in children as we can in adults; and even where we are pretty certain, we shall find it an admirable rule to trust to the general condition of those young patients, rather than to rely on the uncertain knowledge which doubtful local signs often create in our minds. It is often quite impossible to descend upon the testimony of children as to the seat of pain or suffering, and the medical attendant requires to exercise very great discretion and judgment before he draws any conclusion. Let the abdomen of a child be lightly pressed, and it will almost always, when interrogated, reply that it feels pain. Even the testimony of adults under such an examination may mislead us. In a case of fever it may be very important to be safe on this point, as I am satisfied Phave soen leveles and counter-irritants applied when the local signs of pain or congustion, or inflammation have not existed. The turnid and protuberant all domen of a child is sometimes looked upon as an indication of disease, when it is in all respects healthy and natural. The contrast between the abdomes of a child and that of an adult is too well known to need comment here.

Now, there are a few points respecting the management of children in health which if known are not acted upon, and the neglect of them is followed by serious after-consequences. Health is dependent in large measure upon points which may appear very triffing, but which nevertheless if overlooked, from their apparent insignificance, may grow into open dangers.

Disease is early and easily implanted by the parents of children who set at defiance those natural laws upon the observance of which health and strength depend. A young child, like a young plant, requires suitable nourishment and judicious feeding, and without in any way pundering to every fancied aliment, I would were a

[&]quot; In the early part of my professional career I remember an old physician making pressure over the right illus region of a fewer patient when he my in constitution with me, and invisited that make being of the intention was either product or threat-rang. The patient admired that pressure hart her, and accordingly the Unincurrent hydrogery was colored to be rabbed in pight and counting over the supposed seat of machine, and small shows of mercury and Dover's powder given by the mouth. I won desleage from the use of mercury, but not before it had produced slight physics. The progress of the case justified the uplation that the intentions had scaped the losion to which they are so finite. I give this case in point, because delicary of touch, the position of the patient when made examination, the neighbor evidence from a set of symposius rather than from one, are so essential in the diagnosis and treatment of disease.

constant scrutiny and watchfulness. Those children are the healthiest and strongest in every way who are allowed certain freedom in their amasoments and outdoor exercises. The overfood and timid parent shuts up her child in one temperature to protect him from cold and damp, and this often to the rain of his general health, because it is impossible to provide against the variability of temporature in this climate. Very young children should be kept warm, and yet not strangled with tight clothing. Plenty of pure air is most assential for health. When the weather is fine, they ought to be sent out in the air every day, and the windows of their nurseries and sleeping-rooms should be opened twice slaily. In a climate like that of England, however, where we have seldom two days alike, great prodonor is required before exposing children to any risk of cold, as the respiratory tract is so sensitive in early life. Cold alone will originate other evils; the mucous membrane of the stounch and bowels will also suffer, and delicate health becomes established, from which the child either sinks, or very slowly recovers. When infants are taken out of doors a nurse's arms are preferable to a perambulator, on account of the warmth she impuris to them.

If we consider the way in which the children of the poor are brought up in the country, we may learn a lesson from it. When born of healthy parents, they endure with impunity the trying changes of our climate, and resist discusses to which their poorer brethren in large towns and overcrowded dwellings would quickly succumb.* In the middle and upper ranks of life children are often injudiciously fed., their meals are increased in richness and frequency, when they should be of the plainest kind and moderate in quantity. When a child refuses food, my maxim is always to let it alone for a time. The appetite of a child is a good gauge of its powers of digestion, and if you force it to eat against its will the probabilities are that the food will disagree. In such cases the rule we ought to lay down for eating should be, "little and seldom," and not "little and often." The digestive organs require rest in

^{* &}quot;Given the benefit of an outdoor life in a pure atmosphere, and the child of the country persons will thrive, and develop an abundance of blood and massic, abaset without ment at all. The children of the power classes in towns stand upon a very different fluxing, and the stresse and other discuss fluxered in class alleges are obsergently aggressivel by the effects of an insufficient dist."—The Lenot. Editor's Remarks, April 2004, 2072, p. 550.

common with the brain and the organs of locomotion; and yet as soon as derangement of them sets in, the linkit is too frequently followed of administering food and medicine, by which they are kept in a perpetual state of irritation. Some time ago I was called to see a young child in the country, whose friends were alarmed because of a refusal to swallow food. The pulse and temperature were normal, there was neither pain, headache, nor diarrhose. In the absence of any tangible symptoms I suggested to the medical man in attendance that he might be content to leave the case alone. In a day or two the appetite returned, and the child recovered her usual spirits without the aid of medicine.

Unless marked indications exist, I entirely disapprove of the permicious practice of flying to tonics, alteratives, and aperients, as the case may be. Let the food be wholesome and nutritious, or the worst state of health may be engendered; but medicines are foreign to the system, and should be avoided when possible, it being far better to trust to food than to physic. Convulsions, marasmus, abdominal and thoracic affections, are constantly to be

ascribed to improper and insufficient food.

Parents and nurses seem unmindful of the necessity for adapting the diet to the age and strength of the child, by which ther cause much unuccessary suffering, and frequently invite disease. Indigestion, that prevalent source of subsequent evil, is brought about in a great many cases by feeding young children with farinaceous food and different kinds of biscuits, which undergo fermentation, and produce distressing fatulence and disorder of the stomach and lowels. Such diet, in the absence of milk, is obvionely unfit for the purpose of growth and nutrition, indigestion sets in, and the child's hunger seems never appeared; the liver is said not to act, medicine is given, and there is an aggravation of the svil. It loses flesh, and is crying and whining during the day, till the howels start off, producing temporary case. There is the same restlessness and discomfort at night. The extremities become wasted, and the skin hangs in loose folds; the bowels are irregular, and the stools are vitiated; sometimes there is constipation, and sometimes diarrhea, and many children succumb before they reach the age of one year, owing in a great many case, to the manner in which they are fed. Each woman has her own method of feeding her child, and it cannot be denied that some children grow up, and thrive even, under any system that the fancy or caprice of the mother may dictate.

MILE DIET AND STRUKEN,

Composition of with—Contented will, its properties and rathe—Use of will in discuss and some first and makes—Forement forty—Destron—Chairs of a wave—Conteption—Sold arranal—Standards—Air, exercise and sloop—Call bothing—Aperical medicines, there was and shown—Properties of two—Arranay—Solution—Opens——E-content of parameters of chieves—General conclusions.

Mink contains all the necessary ingredients for the preservation of health, and at no period of life is it so valuable as during that of growth, when the functions of assimilation and digestion are most active. The rapid increase of growth in all the tissues, and the waste that also hearly goes on, demand that nonrishment should be supplied at short intervals. We thus introduce into the stomach a fluid which does not tax the tender membrane in its work of absorption, and rare are the instances in which it is not tolerated.

The composition of milk is variable both in quantity and quality, according to the animal which for sishes it and the state of that animal's health at the time. It varies according to the amount and quality of the food, the time at which it is drawn, and a number of other circumstances. For instance, pasture-fed cows yield an alkaline milk, whereas the milk of the stall-fed is more or less acid, and therefore less digestible for infants. The principal ingredients in milk are casein, angar, fat, and salts. So long as the carnivors live on a purely animal diet no sugar can be detected in the milk, but when the diet is mixed, as it is in the human species and amongst different herbivorous animals, sugar appears, and all the different ingredients undergo great variation.

Woman's milk is rich in milk-sugar and fat, but poor in casein."

^{* &}quot;La Prese Medicale says that the researches of Dr. Condereux, of Paris, show that the milk of Suprimum weaper contains a small proportion of salts, but is rich in segur, and especially in fat, derived from the great assumet of only food which they remains to resist the cold in their native limit,"—Medical Press and Cleraler, Potentary 13th, 1878, p. 142.

Mare's milk is poor in casein and fat, but extremely rich in milksorar. Asa's milk contains a much larger quantity of milk-sugar and salts than that of woman's, but more water and less existing and butter. Vernois and Becquerel estimate the casein of ase's milk at 35.65 per 1000, and the butter at 18.50; the case in human milk at 39.24, and the butter at 34.61. After mare's milk, sheep's milk contains the most solids, then cow's, then goat's, then woman's. According to some authorities the casein is a combination of albumen and potash. The great difference between albumen and easein consists in this, that the latter is not coagulated by heat, which precipitates the former. Cassin is coagulated by acetic acid, which is not the case with albumen. Cassin seems to have also the power of combining with the phosphates of line and magnesia, and rendering them soluble. The saline matter of milk, which is nearly the same as that of the blood, is largest in cour's and goat's milk; it seldom exceeds one per cent, and in poor milk it may be considerably lower. Cours fed on bem-root and carrol augment the sugar; the race of Alderneys are said to give more fat, and the long-horns more casein.

In the milk of the cow, goat, and sheep, the proportions of cusein, hutter, and sugar, are nearly the same, varying from three to five per cent. Milk, then, contains three classes of organic constituents; the albuminous, the succharine, and the oleaginous, with those mineral ingredients so necessary for the consolidation and development of the infant fabric. In the human feamle the succharine and oleaginous clonents are present in large amount, but they are affected by the kind of food which is taken and the amount of outdoor exercise. Exercise is said to favor the secretion of casein, and the cattle which faed in exposed situations, and have to take great muscular exercise to procure their food, as in Switzerland and some other mountainous and barren districts, rield only a small quantity of butter, but a larger proportion of chasse. The very opposite takes place, according to Carpenter, when the same cutfle are stall-fed,

Unless milk is perfectly fresh and reliable, it is very prone to undergo lactic acid fermentation, and thus, in becoming soor, a fungoid growth is developed which is highly detrimental to infantile assimilation. The milk so changed might not try the strong digostive powers of an adult, but for an infant or young child it would lay the foundation of delicacy, and invite those diseases which are so ready to attack early life. We are too well acquainted with the cramp, spasm, and indigestion, which attack children who are brought up by hand, and who take their milk out of dirty bottles. The casein undergoes decomposition, and

factic acid is formed in large quantities.

Pure cow's milk should, when placed in a tall narrow glass vessel, be opaque, and of a perfectly white color, having no deposit, and without any peculiar smell or taste. Boiling should not change its appearance. It ought to yield from six to twelve per cent, of cream by volume. This is hastened by adding water, and the cream should rise in from four to six hours. Its specific gravity varies from 1.026 to 1.035. Some authorities give from 1.028 to 1.032, and say that if it falls below 1.026 it indicates that the milk is poor, or that water has been added. The specific gravity is therefore a most important test of the quality of milk. But it must be remembered that a large quantity of cream will lower the specific gravity, which rises again when the cream is removed. Dr. Parkes says, "The average specific gravity of unskinmed milk may be taken as at 1.050 at 60° Fahr., and the range is nearly 4° above and below the mean."

In the adulteration of milk, water is most commonly used, and as I have just said, is to be detected by the specific gravity. Iodine detects the presence of starch, which, like gum and dextrin, are added to give thickness. Assuntto or turmeric is added for the sake of color. Chalk is added to give thickness and color, and to destroy acidity. Cream is adulterated with magmedia and arrowroot. Yolk of eggs is added both to cream and milk. When milk is boiled to preserve it, it may take up from

the vessels that are used, lead, copper, or zinc.

When examined by the microscope, milk is seen to consist of a number of round spherical bodies with dark margins floating in a transparent fluid. When the milk is fresh and bealthy, the globules are fairly uniform in size, they rell freely over each other, and do not collect together in masses. If they do become mingled, and granular bodies of different sizes are seen, whilst a few globular bodies preserve their distinct isolation, it cannot be called good milk. Such a specimen of milk, known as colostrum, is found in the human female after parturition, and if it does not disappear on the fifth or sixth day, the milk must be considered unhealthy and unfit for the child. Of course we may find in it,

pos, blood, spithelium in large amount, casts of lacteal tubes, seeds, fungi, etc.

The number of the globules determines the quality of the milk, and they are more numerous in cow's than in human milk.

The analysis of chemists differs so widely that is a work of this description it would be beyond the mark to give the results of their examination. The practical outcome of their investigations is enough for, our purpose. It is beyond dispute that cow's milk is richer than human, and it must therefore be diluted in order to make it resemble the latter. Further, it contains less sugar, and accordingly a small amount should be added to make up for its deficient sweetness.

When the milk is said it presents just the same appearance as it does when treated with acctic acid, which causes the casein to congulate.

Seeing that the high price of ordinary pure milk may in time place it beyond the reach of the poorer classes, it is important to inquire whether some of the forms of "condensed milk" lately introduced may not be equally autritious, and the milk be unaltered in its qualities, when deprived of the water it contains. These results have been accomplished by Mr. Gali Borden, of New York. He has invented a process for converting milk into a solid, which can be kept pure for a long period, and then by the addition of water be brought back again to its original flavor and consistency. About three-fourths of the water are removed, so that the milk is in a semi-figuid state, of the sunsistency of honey. Mr. Borden believes that neither "desicented," powdered, nor "solidified" milk can be preserved for any length of time. They require hot trater to dissolve them, whilst the condensed milk prepared by Mr. Borden will dissolve at once in cold water.

The condensed milk now known to the public has undergone no change except the removal of the water and the addition of sugar. One pound of the "condensed milk" is equivalent to three or four of the crude milk. It is roughly estimated that about eight million five hundred thousand pounds are unmufactured annually in the eight or ten factories in the United States, or five hundred cases of four dozen one-pound cans daily.

The Anglo-Swiss Condensed Milk Company, carried on in the commune of Cham, is conducted under the Bordon process. It was the first to introduce condensed milk for family consumption, and it has been followed by the Irish Condensed Milk Company, at Mallow, near Cork, and the English Condensed Milk Company, at Ayleshury. The demand is already so great that neither company can meet it.

According to Mr. Willard, "Dirty milk, milk foul with the drippings of the stable, cannot be condensed into a clean flavored preduct." To be so prepared it must be uniformly good. He proeccels to make some interesting observations on the causes that change milk into an unhealthy condition, and allodes to the wellknown researches of Hallier and Pasteur, who consider that this change is brought about by the presence of living organisms in the atosophere of germs from cosspools and putral animal matter, that are absorbed by the milk, in which they grow and multiply. He alludes to the fungi theory, and quotes the words of Professor Caldwell on the deleterious effects the microscours, the eryptosoceus, and the penerillium exert on milk, which is psenliarly susceptible to enunations from decomposing and putrid matter. He points out that the germs fleating about in the atmosphere, if inhaled by the cows, will infect the milk before it leaves the nilder. He cites the statement of Mr. Foster, of Oneish, that cows inhalling emanations from putrid, decaying matter, yield milk untit for making choese. He mentions instances of the milk being tainted from cows passing through sloughs of decomposing vegetable matter. Particles of dirt adhering to the abder, and finally falling into the milk during milking, introduce germs which cause it to decompose and putrefy.* Perhaps the most important point is that notical by Professor Low, of Cornell University. He observed in the hot weather a peculiar rope appearance in the cream which had risen to the milk. Under a powerful microscope it was found to be filled with living organisms, and he traced this condition to the core having slaked their thirst from a stagment pool for lack of clear running water. This water was examined microscopieally, and found to contain the same class of organisms. The blood of the cows also yielded the same results. He then obtained a specimen of pure and good mills, and put into it a drop of water from the stagmant pool, and in a short time an indefinite number

^{* &}quot;Inhaesia are constituen found in milk, and fungi (codium haris and penicalium) are so almost invariably if the milk has been kept."—Dr. Perke's Practical Hygiene, p. 244, 4th edition.

For some most important observations on the changes in some tarils, see Professor Linear's Introductory Addisses, definered in King's College, October, 2077.

of these tiny organisms became developed in the milk. The cows were hot and feverish, as indicated by the thermometer. These observations are highly interesting at the present time, when posound milk has recently introduced severe epidemics of typhoid.

The exact way in which this impurity of milk mentioned by Professor Low was brought about does not materially affect the question at issue. Whether it depends on M. Pasteur's vital or germ theory of fermentation, or on the physical theory which supports the view that communicable discuss are owing to organle poisons neither independently reproductive nor indestructible, is of no moment. Whether the atmosphere contains living germs that induce patrefaction, or particles of dead organic matter which incite patrefaction, does not lessen the danger that milk consumers are exposed to.* Few questions can be of more vital importance to the community at large, than that which establishes the fact of the milk of the costs being rendered poisonous or injurious through the water they drink, or the food they cat.

Very little difference appears to exist between the composition of the condensed milk of the English Company and that of the Anglo-Swiss Company. There is indeed a great resemblance between them in every respect.

Mr. Bartlett, in his paper on "Condensed Milk," from which I have beerowed this analysis, says that all the samples of condensed milk are remarkable for their freshness, and that although some were open for a fortnight in damp and warm weather, no trace of milk fungua could be detected. The best dairy milk, ex-

^{*} See the Journal of the Royal Agricultural Society of England, 1972, vol. xx, p. 103, from which many of the Asserting observations are gathered. The Assertion Milk Condensing Factories and Condensed Milk Manufactories, by X. A. Willard, A.M., of Berkemer, New York.

Journal of Paktic Health, October 19th, 1973, p. 187.

posed for twelve or fifteen boars, became filled with myriads of elongated bodies of fungus sperce, from which the condensed milk is preserved, doubtless by the moderate but sufficient heat incident upon condensing.

To sum up,—the chances of lactic acid fermentation are reduced in condensed milk, and this milk replaces human mother's milk better than that of the ordinary stall-fed cows of large towns, which is often, in addition to its natural unfitness for infant's food, weakened by ministure with water, and rendered numbelsome by adulteration. Several instances have been brought under my immediate observation.

Some patients tell me that their children never throve until they gave them Swiss milk, and the same testimony is repeatedly given by hospital out-patients. Under its use the secretions are kept regular and in good order; the anhealthy, slimy, and dark offensive motions of young children are not nearly so common. I cannot say that there is any real difference in the nutritive or digestive properties of Aylesbury over Swiss milk, but the latter is considered by some medical men to suit better than the former, and so far as my observations go, Swiss milk is the most widely known. Swiss milk contains rather less rasein and rather more sugar, which may make it more digostible, and likely to keep longer. The great advantages of these condensed forms of milk are that they undergo few changes, and are unvarying in their qualities. They are purticularly adapted, too, for hot weather, when cow's milk readily undergoes patrefactive change, and causes sickness and diagrams. Cases are to be not with, however, in which cow's milk suits best, and after children have passed the age of three mouths they do not thrive on the condensed forms of milk. This is partly to be explained on the ground that when cour's milk is employed we dilute it with water, and alld sugar for the first two or three months, but we gradually withdraw the sugar and give the milk undiluted.

Many families are in the habit of receiving their milk in deep jugs with corrow tops, and keeping it in small and confined larders, where it is liable to be impregnated with the effluvia of game, fish, etc. This odor has not the same chance of escape as when the milk is poured into shallow, broad vessels, where it can be kept cooler with a large evaporating surface.

Milk is an organic fluid quickly liable to patrefaction and fer-

mentation, and to become tainted and undergo change of taste and odor when left in the vicinity of cheese, tainted ment, and some kinds of fruit. Poisons are conveyed through the medium of the atmosphere, or through water, and it is no longer a disputed question that milk may also be a disseminator of disease. It can absorb deleterious effluxia, under the circumstances just alluded to, and become unfit for human consumption. When we remember how quickly, in hot weather, milk undergoes patrefaction and formentation, losing its assectness, and becoming rancid in the course of a few hours, we have the clearest proof that organic poisons may readily become absorbed by it. Either by air or by unter the poison of symotic diseases is conveyed, and those persons engaged in milking, who have recently attended on the sick, may even propagate the disease by their hands or by their clothes.

Our experience of the milk spidemic of typhoid fover, in 1878, opens our eyes still further on another point. The poison of cholera finding its way into water, may be spread through milk in the same masner as typhoid; and the atmosphere becoming contaminated with the poison of scarlet fever and measles, may be absorbed by the milk. In short, it is not within the scope of imagination to realize the manner or rapidity, with which the effluxia of contagious diseases may travel, charging the atmosphere with poison, and spreading death and devolution and stricts.

The milk of diseased cows decomposes quickly, and instead of the round oil-globules, which are the only constituents of healthy milk, tolestrum with granular masses, and a large amount of opithelium, are to be seen under the microscope. Casts of the lacteal tubes may also be sometimes detected. It must appear self-evident that few points can be of greater practical importance than to ascertain the chemical and microscopical characters of milk in all cases where sick children are living chiefly on it.

I now come to consider, and that very briefly, what are the diseases in which milk is especially indicated as a medicine. As a dist we recognize its value, and assign to it the first position among all kinds of food. To bring up children healthy and strong milk in some one of the forms I have alluded to must be provided liberally. Constitutional weakness in children is greatly developed by scanty and impure milk; hence we have great mortality before the age of one year is reached. In some of our large manufacturing towns, as Manchester, Liverpool, Glasgow, etc., the mortality of infant life is appalling. The Registrar-General's return for the year 1871, shows that of 112,535 children born within the year, 19,201 died before they reached the age of one year. Regarding infant mortality, Dr. Carpenter, of Croydon, says that "ninety per cent of the children which are put out to dry-nurse by met-nurses, die after a few weeks of hand-feeding. This mortality is induced by the administration of improper food. It is shown by the Registrar-General's statistics that more than 20,000 children, under one year of age, die la England every year from convulsions; that is, ose out of every 34 dies within the year, whilst in Scotland one only in 370 dies from such a cause. The great difference between English and Scotch feeding among the poor is the cause of this variation; the northern babies are not stuffed with faringceous food before they are able to digest it; Scotch mothers scarcely ever feed their habies with anything else. than that provided by themselves in the first few months of their lives, and the result is, that convulsions as a cause of death, are comparatively rare in the first year.""

We know that in some children, and even in adults, the digestive functions are so enfeebled that milk cannot be assimilated. The occasional aversion to milk is also well known, and the dislike to it cannot be overcome. I saw one child, six months old, who could digest about half a plut of milk daily, but if this quantity was increased severe sickness followed, and the attempt to give more with lime-water or plain water, or Dimesford's solution of magnesia, was of no avail. It was impossible to give it in any large quantity, and the diet was supplemented by veal broth. chicken broth, or weak beef ten. In some adults, severe discomfort, weight and indigostion, follow from the continued employment of milk, and it cannot be denied that ordinary cone's milk does tax or interfere with the digestive power in some cases if taken in any considerable quantity long together. It causes weight and heaviness and in some cases constitution, and where this is so, aversion or dislike is certain to easue. Brandy, soda-water, lime-water, dillwater, etc., have been employed to overcome this objection, and in a great many instances the addition has been successful, and the congulation or curding in the stomach has been prevented.

Some of the Carses which produce Infant Mortality and Domitational Weakness, by Alfred Corporter, M.D., Public Health Journal, June, 1873.

In all those diseases that are of a consumptive or wasting character, and where emeriation is going on, milk is extremely ralnable, suitable to the digestive organs, containing all desirable elements for the requir of the body, and best compensating for its waste.

In cases of extreme debility and manamus, chronic dyspepsia, carcinoma and niceration of the stomach, gastrodynia, etc., milk is ear short anchor; solid food cannot be tolerated by the digestive organs, and if we had not a remedy like milk, our patients would literally die of starvation. I can call to mind one severe case of gastric pain (neuralgia of the stomach) in which milk was the only food taken for upwards of four years; nothing but a rigid adherence to this simple diet procured the patient case, and gave him rost at night, instead of the agonizing suffering which he had endured for years. This patient had long ridiculed the idea of living on milk; indeed, it is only in continued states of ill health that patients can be brought to understand that milk is possessed of extremely nutritive qualities, and is sufficient to maintain life.

As life advances, and more especially towards its decline, when the tissues are undergoing degeneration, and the eliminating functions are becoming impaired its in structural degeneration of the kidney), milk may temporarily arrest or lessen the activity of these changes and prolong existence. The skim-milk treatment of diabetes is fresh in our recollection, and whatever doubt may be thrown on its virtues as a therapeutic agent, there can be none as regards its nutritive and non-irritating properties.

In nexte diseases of the febrile class, and nervous diseases generally, milk is a powerful restorative. In the diarrhosa of enteric fever and some other profuse discharges, hazmorrhages and loss of blood, and great lagration, we have in milk a valuable remedy. By increasing the general nutrition it has the effect of diminishing the discharges from the mucous surfaces.

Among children of well-to-do parents, and in the higher ranks of life. I have repeatedly seen the advantage of giving them a good supply of milk morning and exening, before going to bed and on getting up. The appetite has improved, and each meal has been reliabed and digested through the milk, which has acted like a toric. These facts are, however, known to all of us, and similar instances occur in our practice every day.

This brings me to say that milk is constantly underrated by

parents and mothers, and credit is given to certain patented "corn-flours" to which they are not entitled. We may lay it down as a golden rule that unless food is easy of digestion it fails to be nutritive. Many of the forms of food advertised for children are said to contain a large percentage of earthy phosphates, and to be singularly sich in nitregenous or plastic materials. They may be of service where milk is also fruity supplied, but without it they are of questionable value, as they contain a large proportion of starch, which young infants are incapable of digesting. The salivary and panereatic glands do not reach their functional development until the infant has attained the age of eight or nine months; and as starch requires to be acted upon by their secretions before it becomes converted into a soluble sugar, it follows that all farinaceous foods are incapable of digestion, and therefore worse than useless before that age is reached. The true function of the sallyn is to convert starch into gincose or sugar, and unless it is so arred on by the salivary or parcreatic secretions, it either passes through the bowels unchanged or undergoes lactic acid fermentation, producing flatmence and spasm by the quantities of intestinal gases which are generated as a consequence." Experiments have been conducted to prove that the saliva of an infant four or five mouths old has no action on insufficiently cooked arrowroot, sago, taploca, and the so-termed "com-flours," but the solivary secretion of an adult has considerable transforming power. Still chemists are of opinion that they are not suitable for any age,†

In very young children milk is the only nourishment required, so nicely adjusted are its component parts, but until we can con-

It is important to alliable to this fact of enliving secretion in infamile life, "For the first few months if appears that no saling at all is secreted; and it is may under natural electrostations, from the character of the food, and the electron of manifestary organs, that it is not required."—Proy, the Food and Diestics, 1870, p. 227.

^{*} Some Experiments on the Digostibility of Starch by Indians, Journal of Public Health, August 1972; p. 111.

[&]quot;The digestion of starch is recomplished by the solive and generative joice, both of which are rich in discuss. Discusse also exact abundantly in the liver, and in smaller quantities in the intestinal joice, in the blood, the arine, and apparently in all the intestinal joices. Discusse from all these diverse sources appears to not substantially in the source master on starch, changing it by a programine hydrodynic into segar and districts."—Laminum Lotares on the Dipotics Ferment, by W. Ballerte, M.D., F.R.S. April, 1894.

vince mothers and surses that a child can grow and thrive on it, we must expect the substitution or admixture of other foods. Sometimes we are told the milk does not agree, and on inquire we find that either the nurse or the mother, if suckling, is out of health, and the milk as a consequence is defective and ill-suited to nourish and sustain the child.* Every mother should know the importance of wearing her child at seven or eight mouths, because suckling beyond this time is likely to damage the health of both. If the mother can nurse her child so much the better. If dolleate she should not suckle during the night, as it will disturb her rest and exhaust her. When, however, the mother's milk is scanty, she should not attempt to noursh the child entirely, but give warm milk and water out of a bottle. If she cannot spekle it, it should have equal parts of milk and water, and it is a good plan to boil it before putting it into the bottle. Let it be sweetand with half a teaspoonful of sugar, and see that the tube and bottle are well rinsed out, and kept perfectly clean. It is a had plan to overfeed a child at one time; the sixth part of a pint of milk is enough for a meal, if the child is under a mouth old. If the milk disagrees, a tablespoonful of lime-water, or sometimes the same quantity of dillownter, may be advantageously added to each bottleful. Regular feeding is of great importance; till the child is two mouths old, once in two hours will be often enough, and afterwards once in three hours; of course if the child is very delicate, it may require to be fed oftener, but it is an error to put it to the breast every time it cries.

^{*} Much of the milk brought from the country is impure. Many children purish the first year of their existence from full are of the digestive cagues to support them, and when brought up by hand or underful then are power to die of branchitis, distribute, whereping-cough, etc. As to furthermore diet, much may be unged for and against it; it may cause children to both plump and fat, but if too long continued the blood because this and assemble, and exhaustlon, and over fatal synappe, are not underposently put with in these children.

At the persent day, however, furianceous feeds, as once fierar, assessment, etc., are indepented, if not altogether condenses of by purey persons as undefor antition. Liebig and some other chemics advocate this view, which led to the employment of too ninogenous a dist, and so an appearance error crept in. Facts must speak for thermodyse, and it cannot be desired that we see some young children whose flesh-forming power appears to be due to the notifition of starolay food. Abundant instances of the Kind are to be men with among the rural population of England. It is a point descring consideration whether a too exclusively minual dist may not sow the seeds in early life of a time arid disthasis, and develop good and Bright's disease with advancing years.

In treating the ailments of suckling children, we neglet to examine the milk of a wet-nurse very closely, for any error in diet on her part, or any indiscretion in drinking, will be certain to be felt by the child she is bringing up : mere emotion, auger, or disappointment will influence the lacteal secretion. eramp, spasm, flatalence, constitation, and distribute in young children can constantly be trured to dyspepsia brought on by the milk, or the mental condition of the nurse, and all the medicines we may prescribe will prove but palliatives so long as this state of things is suffered to go on. In selecting a wet-nurse it is very important that she should be ju good health and spirits, and free from constitutional taint. She should be fully groups, and as a rule, not less than twenty-two years of age. Lencorrhon is an objection, and any evidences of strumous disease, as sears in the neck; then the most rigid inquiry should be lustituted as to whether she he free even from the ampleion of syphilitic disease. The evidence of synhilis is somewhat difficult to find in the absence of any notive manifestations, but it is always well to search for marula and alceration about the fauces. A few cases in illustration of these remarks may be here quoted.

Case I.—A lady consulted me in Pebruary, 1868, about her infant which was five months old. It was not thriving to her satisfaction, the skin and muscles being lax and flabby, the bowels frequently relaxed, and the motions concilines concisting almost wholly of morns, with an occasional streak of blood. There was also a good deal of redness and excoriation around the muss (Intertwies). The nurse who suckled the child assemble a fairly benithy woman, but a microscopic examination at once showed that the milk was very deficient in the number of diligiodules, and therefore unfit for the purposes of nutrition. I recommended must milk to be given alone, as digestion was weak and cours' milk did not agree. The child gradually improved from that time, the bowels becoming regular and the motions healthy.

Casa 2 .- An infant, seven months old, was subject to occasional

The sulk of the us often suits with the follower digestion of an arbit ; it is righter in super and whole sults, and contains how altroprocess marrier and for their cost until Though it is therefore adopted in particular costs to none infants from the facility with which it is digested, in composition is not rich causing for a strong and thriving child. For further information on this point see Dr. Pavy, On Food and Distation, 28 edition, 1975, pp. 185–529.

attacks of vomiting, cramp, and flatulence. The motions were never two days alike, sometimes being hard and pebbly and lightcolored, at other times loose and frequent. The child was niways areasy after food, unless an attack of diarrhoa or vomiting came on, when it usually became quiet or fell asleep. The child was fed on cow's milk, sweetened and diluted with water, and biscults were generally added. It is quite clear that this method of feeding did not agree with it, indigestion being a marked feature of the child's sufferings. It was found that the malk was not good, and in addition to the biscuits which disagreed, and increased the amount of flatuience, the child was fed at irregular bours, and the stomach loaded. New and good milk was now procured, and a small quantity of dill-water was added, all bisenit food and farinaceous articles being solemnly forbidden. The child almost immediately began to improve, and at the sud of two months had grown plump and strong without a sign of discomfort.

CASE 3. - A luly requested me, in April, 1868, to visit her child. who was then six months old. The child was fit and plump, and always inclined for food, which he took greefily. When he was not enting he fell asleep. The only complaint made was that the howe's were habitually confined, and that in consequence, aperient medicines had to be constantly resorted to. The motious were very hand and pale, the child often crying when straining to empty his howels. It was evident to me that the child was overfed, and I persuaded with some difficulty that he should be restricted to milkand-water. In the shape of medicine nothing was ordered except a Iwo-conce enema of seap and water to be thrown into the lowel early every morning, and pressure to be applied at the anal aperture, that it might be retained a little time. This was enough to act as a gentle stimulus to the liver, and to regulate the bewels, without any other scode of treatment. Here was a child of sound and vigorous constitution, that would have thriven on that upon which another child would have starved, and when this simple regulation of diet was enforced, no further remedies were required.

Instances of this kind are repeatedly met with where constipation is the chief symptom. The child's borrels act once in two or three days, whilst the appetite is good, and the condition is in every other respect healthy. The motions are deficient in moisture, and painful to pass through the anus, which becomes red and tender. The little sufferer screams in its straining efforts to evacuate the impacted mass. This nursery trouble may set in some after birth, and add to the risk of teething. The liver in these cases does not not well, and the small insistines fail to furnish their due amount of secretion, and the rest of the intestinal tube becomes sluggishly passive in propelling its contents. Overfeeding enous this troublesome sonstipation as often as underfeeding induces diarrhous and exhaustion. But the cause is not always ascertaluable. In some cases I have been inclined to regard it as constitutional. It occurs occasionally where the mother's milk is bealthy, and microscopically faultless.

The mother may be weak and languid, notwithstanding the good character of her milk, and if her health is not attended to the milk will become impoverished, and the child suffer in other ways. Mere constipation in the child is no eridence that the milk is at fault, but when given too frequently and abundantly it deranges the hepatic functions. In these cases of otherwise healthy children a saline aperient given at bedtime, and repeated early in the morning is a good remedy." After a few doses the bowels begin to not more regularly, and the motions become soft. In alternation with the mixture the soup enema is an excellent remedy. As the nurse sits with the child in her lap before a fire, friction with the hand for a short time, morning and evening, over the abdomen acts as a capital stimulant to sluggish bowels. We now and then meet with another class of cases in which the motions are moist and of proper color, but considerably larger and firmer in consistence than we expect to find in infants of five or six mouths old. The howels will not act without an enema or an aperient of some kind, and parents become alarmed if this goes on, as it often will in spite of any treatment, till dentition sets in, When there is no mechanical obstacle, as hernia, imperforate rec-

Our to two unseparatials to be taken at holding and in the early morning. For a child five or six months old.

tum, or invagination, the fault may in most instances be attributed to the food. If the general health of the child should keep good, no harm will follow from this form of constipation. The aperient must be varied from time to time, and the enema used in change with it. When simple remedies fail, a tempoonful of the decretaloes comp, or a grain or two of seammony or julap, or even an occasional mercarial will rouse the torpid liver and inactive viscers, and premote the passage of falls and muchs. It sometimes happens that immediately a tooth penetrates the gum the symptoms improve and the constipation departs. In other cases the constipation is troublescene, and an enema has to be given every third or fourth day till the child can run about and take exercise.

Milk mixed with broad, as children grow older, is very exerlent. For my own part, I have much faith in the familiar expression, "Bread is the staff of life;" and if we want to know its nourishing properties we have only to look at our village population. Many healthy children from the age of three months thrive on this diet, and grow up strong and healthy. Scotch outment is another valuable article of diet; it is very nutritions, and regulates the action of the lowels better than anything else with which I am acquainted. It should be mixed with milk, and may be

given to children from the age of one year.

Of course, differences of situation necessitate differences of treatment, and children of delicate parents, living in a vidated atmosphere require a special diet. At seven months old the child may have milk, to which Robb's biscuits or Liebig's food may be added. or well-baked bread. The child should have plenty of warm milk in addition. At ten months old it should have weak broth or heaf tea. When a year and a half old it may have pounded meat, with a little gravy, or meat cut up very line. Much will depend upon the natural strength and constitution of the child; but solid animal food should not be given till it is two years old. Hospital patients have repeatedly told me that milk alone would not satisfy the hunger of their children, and before bottles came into fashion I have often seen strong and healthy children, at four or five months old, being fed with milk thickened with bread; whereas, among the very poor in rural districts, gruet has in many instances been the only article of diet. A deliente child would break down under this system of feeding, but in those who are thriving and breathing pure air it has no prejudicial effects. Whether the

child be strong or delicate, milk should be the chief article of diet till the age of two years; and the continuance of debility should be an indication to persevere with the milk pure and alone. It is a popular error among mothers that milk must soon give place to solid food, and yet those whose practice lies among children will offen reserve a child at eight or nine years of age, with a good appetite, eating meat three times a day, grow thin, pallid, and languid. These children have delicate digestions, the tengue is indested at the sides, the back coated with a whitish fur, and there are superficial abrasions of the mucous membrane, all judicating extreme forbleness of digestive power, amounting to slow starration." Place such a child on a dist of milk and he begins to thrive at once: his tongue gradually improves, his bowels are regular, and he gains flesh and strength with surprising rapidity, If you can induce the parents of such a child to give him a businful of milk-and-bread for breakfast instead of tea, and let him have well-mineed mutton or chicken once a day, and cod-liver oil, he will throw off his delicacy, and the rost will have enabled his digestive organs to gain strength,

When children have out their incisor touth they are liable to feverish discomfort and restlessness; they alarm the surse and the mother by starting in sleep and exhibiting a spasmedic movement of the lips and cyclids. If we examine the month in such cases we shall generally observe that the gums are red and tender, and although other teeth are not appearing nor distending the gam, they are probably at no great distance. It is always well to puneture this inflamed gum with a lanest, and to give a freely setting purge. If the child is strong enough, let it contain a grain of calored, for, much abused as this drug is, and told as we are on evidence that seems conclusive, that it does not increase the scoretion of bile, I know not where to find any purgative or alterative medicine that acts so efficiently in many of the diseases of early life. Let it be given on an empty stomach, and do not deny the child if roll mough, a drink of cold water, or of toast and water, This is, however, at best a critical period with children, requiring much care and watchfulness on our part. The nervous system is easily affected, and the digostive functions are readily upset, which would be less likely later on. The extreme frequency of convul-

² See Chap. XVI, On Indepension.

sions in early life should always be borne in mind whenever the system is out of order, and the medical attendant should never lose eight of the liability to them in young children, however well a case of illness may be progressing.

The balance between health and disease is so delicately adjusted in early life, that a very slight disturbing cause will incline it to one side or the other. Health and disease hold close relationship, and we are often perplexed to know where one easls and the other begins. Where medicines are necessary, it is very important that they should be prescribed in as agreeable a form as possible. A medical man will often get much scralit by ordering his medicines pleasant to the taste; and there are very few drugs really necessary for children which cannot be given in a pleasant form. Some practitioners there are, however, who seem never to have considered this matter, and as a consequence, many of their medicines are thrown saids by the mother or the name, who, rather than hear the shricks of the child, gives up the effort to alminister them. I think a certain degree of fact and judgment is required in prescribing for young children.

The habit of giving young children wine and beer is a very had one; their digestive organs require no stimulants to aid the process of digestion, as is the case in after-life, when the stomach loss its tone and becomes enfeelded, and where a glass of wine is necessary before the patient can either fancy or digest his food. Some of the strongest and healthlest children I have ever seen have been those whose diet has been the plainest, and where stimulants, theree, and postry have been ranked with objectionable nursery drugs, as gray powder, confial mixtures, and texthing powders. In illness, and especially in neute disease, where time is valuable, stimulants may be demanded; and in my own experience. I have several times known young children recover from acute diseases in consequence of their administration. The following is a typical rate:

Case 4.—A healthy child, ten weeks old, was suffering from troublesome catarrh, in February, 1870. The child was resilous and could not suck comfortably, owing to the obstructed state of the nostrils. Brouchitis, confined to the upper tubes, ensued, and alarming prestration set in. The cough was very harassing from the accumulation of phlogus, and there was great flataleness and irregularity of the lowels. The mother, at my request, reluctantly consented to give up suckling. The child was fed on ass's milk, of which he took two pints in the twenty-four hours, mixed with four small tenspoonfuls of brandy. He was also fed with a little beef ten three or four times a day, with a few drops of brandy, This last some appeared to irritate the bowels, and was, therefore, discontinual. In the shape of medicine, he took half a grain of carbonate of ammonia in syrap of tolu and water every four hours. The temperature of the room was kept at 70°, and, what I have found of great value in the pulmonary affections of young children, the cliest was corned, back and front, with cotton-wool; and this was allowed to remain on during the critical state of the child's illness. Beyond attention to cleanliness, the child's clothes were not removed during the illucas. This is a great point to look to in dangerous disease. The fatigue and exhaustion that result from frequently drossing and undressing a young child are not emsidered, and the repose and rest, which are valuable aids to treatment, are altogether overlooked. The temperature ran as high as in genuine fever, but on administering suitable food and medicine it fell, and the child rapidly improved. I have known this high temperature cause much alarm among medical men; but it must not decrive us, especially with children, who, from more gastrie disturbance, will, in the course of a few hours, become harning hot.

There is nothing more important than air and exercise for childdren. When shut up in the house they become fractions and irritable, losing their color and appetite, and becoming very wayward and difficult to manage. The natural disposition of a child may be greatly determined by being habitually shut up in a room, and deprived of proper air and exercise. In the house it soon tires of its amusements, but when carried in the open air fresh objects continually meet its eye and orguge its attention; digestion is improved and healthy sleep promoted. Children who live in London and other large cities exhibit in a most remarkable degree the salutary effects of country air, and, when they have been kept from

^{*} Life and health walk hand in hand. Health is marking but integrity of the prisons is nothing but no offence and abbreviation of it. Gyunnacic experies will not under all discussionable be encounted, but, orders probes, it will be in creating first term.

Exercise, whether pleasing or not pleasing, it ognilly advantageous. The same degree of perspiration, the same mornior notion, is produced; the same results of sound repose, strength, and builth recoverity follows."—Physical Education, Machillers, pp. 147 and 358, September, 1878, No. 180.

falling into ill health by the tenderest and most judicious care, they revive under the influence of change with a rapidity that is truly astonishing. In densely populated places foul and impure gases are breathed into the system, and carried into the blood, which only the pure oxygen of the country can remove.

If eating a heavy meal on going to bed, or indulging in tea and coffee after a good dinner, tend in some adults to cause sleeplessness, melancholy dreams, throbbing headache, and cardiac pulsation, sending children to led exhausted and with empty stomachs will also equally cause discomfort. Such children dream, and are restless in their uneasy sleep; they toss the clothes off, and are provish and tired when they are roused to dress and get up in the morning. If jaded by long walks and the strain of school, interrupted digestion is indicated by fatigue, and they are sent to led too exhausted to obtain refreshing sleep. Children should have a light meal half an hour before retiring to bed; a snodwich or a slice of bread and butter will in most cases suffice to satisfy the eraving stomach and allay the fainting empty feel. If food, however nutritions, is given them at this time, when they are too exhausted, and the nervous force which should have been reserved. for the stomach has been expended in active locomotion, we only aggravate the evil. The feeble stemach as much recents the presence of food as the weak eye rescuts the light. Let us bear in mind that a child requires more sleep than a grown-up person, because tissue change is much more energetic, and the organs demand more rest for their repair and growth. The digestive system, too, requires the frequent administration of suitable food, that the absorbent process, with its varied chamical changes, may be actively sarried on.

Cobl-bathing is another aid to health, and the sooner this is begun the better. It is the foundation of much subsequent good health. With a good circulation there is nothing more calculated to keep the skin in a healthy state; for on it depends to a very great extent the regularity of every function in the child. When early practiced, children will grow up to revel in the luxury of sold water, coming out of it with a skin at first mottled like the slate-gray lines that permente hard scap; and subsequently under friction, gradually becoming red, as the blood passes more quickly through the capillaries. The toxicity of these vessels is increased, and that relaxation and debility which render them helpless to

contract on exposure, is in a great measure guarded against.
When the latter condition exists, children are very liable to cold
and affections of the respiratory organs. A cool, clastic, and firm
skin is an indication of health, and often by it alone the medical
attendant is able to decide on the state of his little patient.

Daily intercourse with disease can alone teach us how to prearribe. Aperient medicines should be delayed as long as possible, but if they must be resorted to they should be of the simplest kind; and whenever I can, I always endeavor to avoid bulky pourders. Frequently they are not properly mixed, and as often they are not swallowed, and so we are disappointed in our cases. The aromatic syrup of semu is not difficult to administer, and the syrap of rhubarb is enough to move the bowels of young children, regularly and officiently, if continued a little time, and there be no necessity for promptitude in our measures.

Honoy or treacle spread on bread is a favorite laxative with come persons. The syrup of rosts may be given with an equal quantity of easter oil, and there are few children who will not take it. Infinits of a few weeks or months old will suck readily a teaspoonful of a mixture made with easter oil, white sugar, and carbonate of magnesia, with two minims of oil of dill to the ounce (Form, 28). It is a good combination where there is costiveness. and painful flatulence. Dinneford's solution of magnesia is a safe and useful antacid and aperient for young children, dispelling flatulence, and gently stimulating the peristaltic action of the bowels. An equal quantity of syrup of chubarb may sometimes be advantagescaly combined with it. In feverish states, with constitution, young children will take a mixture containing a grain or two of nitrate of potash with a few grains of sulphate of magnesia, when sweetened (Form. 8). In hot and excited states of the system we may order with most excellent effect, a purgative and alterative lozinge composed of one grain of calonel and two grains each of scanniony and juliqu. It is well to order it to be given the last thing at night, as it then empties the lowels fully and effectually early in the morning. It causes copious and full evacuations, freely unloading the liver and small intestines; and in cases of Severish excitement, it has acted in my hands like a charm "

How frequently do we see the ill effects of aperient medicines,

^{*} See Chap. XVII. On Consequence, where this subject is more fully considered.

adopted and had recourse to on any accession of real or fancied allment. If the medicine employed is simply of a laxative character, and the child is in even tolerably fair health, the mere evacuation of the intestinal contents can do no harm, and the child is sone the worse if not the better for the experiment. But many are not satisfied with this mild class of remedies, and they select some cathartic purge which throws the intestines into riolent commotion, unduly stimulating and exciting the muccus follicles, and irritating the whole intestinal tube. The stomach, liver, and paneress, are disturbed in their quiet functions, and the furred tengue is a sign of weakness and temperarily deranged stomach, from the unnecessary employment of medicine. Such medicines are enough to enfeeble and suspend digestive power, and to create as much disturbance as a mass of indigestible matter in its passage from the stomach through the housels.

Children are often brought to us, looking pale and languid, with a dark aroofa under the eyes and a furred tongue. We ascertain, perhaps, that the trustworthy nurse considers them billions, and gives them gray powder once or twice a week. They have very little appetite; the bowels do not set for want of power; they complain of being tired and are gizd to go to bed. These are the cases which run into assemia; enlarged glands spring up about the neck, and if there happen to be a strumous taint, we get abdominal or pulmonare disease. The syrup of the hyperhosphite of iron, with or without quinine, is very valuable, and Parrish's chemical food (Syr. Ferri Phosph. co.) will effect, in such cares of pure debility, a marked improvement in the health and appearance of children. The syrup of the lodide of iron, in cases of amenda with a disposition to swellen cervical glands, is a wellknown but overrated remedy. I am very doubtful if it possesses any real value. We may employ it in many cases of chronic cough and debility, with or without a few drops of specacuanha wine; where we have any reason to suspect a tubercular origin we may give it very early. The Vinum Ferri is a slightly astringent preparation. We may sometimes prescribe with good effect a steel powder, consisting of one grain of sulphate of iron and three grains of augur. Children take it with a relish, either in water, sherry, or ginger wine. It is a cheap tonic, and is very available for hospital patients. A most excellent preparation is reduced iron (Ferrum Redactum); it is a valuable remedy in animia, chorea, and

general debility. A grain or two may be given on bread-and-butter twice or three times a day. It has the advantage of being tasteless, and a very small dose is required. Then there is the iron lowenge (Trock. Ferri Rednett), which no child will refuse to take. Each lowenge contains one grain of reduced iron, mixed with refused sugar and gum acacia; one may be taken after each meal.

It is not advisable, as a rule, to prescribe for children preparations of iron with quintine, as the latter being objected to, the medicine runs the risk of not being regularly administered. Iron, too, is much more valuable as a tonic than quinine; it is less stimulating, is a good blood restorer, and strengthens and invigorates the nervous and circulating systems, on which the regular performance of all the hedity functions depends. These forms of iron regulate the bowels by the gentle stimulus they impart to the muscular fibre of the intestines, and the alteration they effort in the constituents of the blood. Dissatisfaction is sometimes felt at the apparent inertness of those agents, but this often arises from their being discontinued too soon, or not given regularly. We lator under great disadvantage in all chronic forms of illness, as the necessity to give medicines according to the rules laid down by the medical attendant does not seem of sufficient importance, and where cases are tedious and protracted, friends and nurses are apt to grow negligent and indifferent. In acute forms of disease they are more regularly given, and homes they often obtain a credit which is not their due.

Antimony is a medicine seldom required in the aliments of young children. It is so depressing that unless the disease is orgent, as in crosp, and a few other diseases, we may dispense with it and choose ipersonalise, which is not so lowering, frequently as effective, and much more manageable.

Emeties are often required for infants and young children, who vomit readily, the act being accomplished without the straining and distress which are experienced in adults, because the stomach is not so conical in form as in later life, but is more elongated, and resembles rather a dilatation of the intestines. Emetics should be withheld from children with head affections; in peritonitis or acute also minal discuses, or where there is great debility; but in the early stage of many disorders, as in croup, they promote the free action of the skin, and at a later stage favor the expulsion of false

membrane from the traches. In whooping-cough, preumonia, beonehitis, and the early stages of the exanthemata, emetics are of great utility in reducing the force and fulness of the pulse, in lowering the tension of the vascular system, and in promoting secretion. The thick and tenzoious secretion which olings to the glottis in whooping-cough becomes thinner and more easily detached by their action, whilst the hypersemia of the bronchial mucous membrane is lessened. Emetics are serviceable during the invasion of acute toosillitis; in some forms of acute indigestion and dyspepais they are also useful by exerting the liver to free action, and removing morbid secretions from the stomach. An emetic repeated twice or three times a day, followed by a little warm water to insure its complete effect, is preferable to one large dose.

Solatives are remedies not to be recklessly employed in the discases of young children. The sooner ignorant minds are made aware of the dangers they incur in giving these medicines without medical advice, the more chance is there of rearing strong and healthy children. The influence of the profession should be brought to bear upon the indiscriminate sale of soothing or toothing powders, and the public should be cautioned against them. Under the prevalent and frequently erroneous notion that children are suffering from their teeth, a poor woman, to keep her child quiet, or to get a night's rest herself, gives it a teething powder to send it to sleep.* Where there is great excitement of the nervous and vascular systems solatives are sometimes employed with great advantage. Hyoscyamus, hydrocyamic acid, and the compound tincture of campbor are so important to us that we should find it difficult to get on without them. Tincture of opium, however,

[&]quot;In November, 1974, four children died at Bourbert after taking 'teething powders,' and death was preceded in all of them by stoper, drownings, and insensibility. These damperous symptoms set in mon after the proders were given, and were clearly due to an american of opions. Duren's powder appears to have been the tiens to which opions was administered."—Bound Medical Joseph Nov. 18th, 1874, p. 622.

[&]quot;In 1886 I also was distressed to find the use of opinion among children very provalene in manufacturing districts. In this case the motive was not criminal, for the practice had arisen in ignorance of its bad effects. But it was not difficult to trace a large annuary of direct and indirect mortality to this permission crosses. Among children the administration of opinion under the names of quinters and worthers, is marriy as destructive to bealth as the executive met of absolute stimulated enough islate. The cruzing for both arises from those deprecing physical causes of disease which absolute in cities."—Dr. Lyon Physics, On Smittery Belleria, Social Science, Congress, Gilagere, Oct. 30, 1874.

requires to be given with the utmost caution. In administering fincture of opium by the month it is well to observe the rule of giving the sixth or fourth of a drop to an infant under three months, and to repeat it as occasion may require; half a drop for a child of six months, and a full drop for a year, adding a drop for every year of the child's age. I once prescribed six minims in an ounce and a half of demulcent mixture for a child fourteen weeks old, one teaspoonful to be given three times a day. This was enough to make it so sleepy and heavy, that the mother said she could not keep it awake. When roused, it opened its eyes, and then fell off to sleep again. Instead of having six motions during the day, it had three. Fortunately we can often get on without the internal exhibition of landauum, which is a remedy we regard as certainly dangerous to young children if incantiously given. A child will, however, take a dose of calomel with far greater impunity than an adult, and be infinitely less likely to run any risk: from selivation. Bromisle of potassium, and hydrate of chloral, are now recognized to be of great value in the treatment of children's discretes.

To sum up these points, it is to be observed that I have laid stress-

 On the peculiar forms which disease assumes in childhood, as distinguished from the forms of the same disease peculiant in adults;

 On the rapidity with which functional sometimes passes into organic mischief, during the period of hodily and mental development; so that no allment should be considered too trivial to receive attention;

 On the great importance of looking to constitutional symptoms rather than to local derangements, because the primary disturbance may be of greater moment than the secondary effects;

 On the necessity of looking to diet, and adapting the quality and quantity of the food to the age and natural atreagth of the child;

5. On the importance of selecting medicines, when medicine is absolutely demanded, from that class which will support the bodily powers and assist in maintaining each function as nearly as possible at a normal standard. It is my object in the following pages to carry out these general principles, and to show how they are to be adapted to particular diseases, and what exceptional treatment each disease seems to warrant.

CHAPTER III.

ACRYR AND CHRONDS INSILIAT.

Diseases may be advantageously divided into two great classes, the acute and the chronic. Although we recognize a connection between them and an interdependence, there exists, not withstanding, a wide difference. The importance of defining the line of demarcation enunot be over estimated. Between the duration of acute and chronic disease there is another distinction. An acute disease like hemorrhage or cholora may terminate in a few days or hours, whilst a chronic disorder, as asthma or rheamatism, may continue through the greater part of life. An acute disease is, so to speak, an emergency, and immediate measures are necessary to meet it. Chronic disease being, by its very definition, slow in its progress, gives us time to consider; during which time emergencies may arise of a character generally but not always to be described as subscute. The management of the acute is comparatively simple, the management of the chronic is often a complex affair. There is the treatment both of the chronic condition and the different intercurrent maladies which arise in its course. Since these secondary maladies are often more prominent than the chrome morbid mischief which underlies them, the primary state may be overlooked. The character of the disease itself gives the main lines by which we must travel, and which may be fairly clear; but when secondary complications arise, they furnish contingencies which tax to the ntmost alike our acquired knowledge and our individual skill. This involves the true comprehension,

not only of the acute mischief, but also of the chronic condition, which lies beneath and influences it. An apparently simple inflammation of a joint in a healthy child becomes a wonderfully different condition in a child who is naturally strumous; so that the state of constitution has to be recognized in every child, who her its ailment be acute or chronic. Indeed, constitutional debility and the strumous and syphilitic diatheses are pencically chronic diseases. The manner in which they influence complications is only too well known; and the fatal result of a simple neutral affaction, not in itself severe, may be entirely due to some chronic morbid condition underlying it.

The terms acute and chronic are, after all, somewhat arbitrary. They seem to imply two sets of discuses perfectly distinct, and having no exact relation the one with the other; but in reality there are intermediate stages or degrees of discuss which these two terms do not include. Subscente is a term used to signify the duration of discuss when it is neither actually acute nor chronic, but something between the two—a relic of the acute affection, with a duration shorter than the chronic.

Indeed, gente and chronic are terms used as usuch to convey an idea of the duration of the morbid affection as of its intensity. Diseases called by either name, may belong essentially to the same great family. Acute pneumonia may become chronic pneumonia, acute pericarditis obronio pericarditis, acute rheamatism chronic rhounsatism, and acute rephritis may terminate in the chronic form with albuminuria. Many other illustrations might be furnished. "In a general way, we call discuss that spring up in the system suddenly, or in a brief space of time, or that are rapid in developing their characteristic phenomena, or are of abort duration, arele; and those which have the reverse characteristics of slowness of increasing, mildness of manifestation, and longuess of duration, Aronic. These distinctions, however, are obviously not of an essential or fundamental kind, as ther have reference not to the nature of the phenomena so much as to the mode of their manifestation and their degree. Indeed, rearly all the discuses termed acute present themselves in the chronic form; so that we may almost say that we have two marked varieties under every individual nominal disease, namely, an acute and a chronic variety."*

^{*} Nature and Art in the Cure of Eksesse, by Sir John Forbes, 1857, p. 62.

Some final diseases are essentially of a chronic character, as the sound forms of hip joint disease and mesenteric disease; the circulation is depressed and low, and changes proceed slowly; whilst in many constitutional diseases, as fevers, inflammations, etc., the tendency is, to produce besions and such changes in the secreting functions of organs that they become temperarily or permanently deranged, and health does not return till the natural secretions are seen again restored, and the parts involved have resumed their normal state.

The term scale may be applied to a class of affections which are largely inflammatory or zymotic, including the whole list of febrile and eruptive diseases. The condition may also arise from severe shock as after surgical operations, and the patient may actually sink in consequence, or it may be caused by exposure to great heat or cold, or sudden and severe prostration, as in bronchitis during winter; or in the severe gastric disturbance caused by the presence of indigestible food in the stomath.

First, as regards syretic affectious. The rapidity with which the rise of temperature comes on is in itself instructive. Where the evidences of any acute specific discuss are wanting, and there are no obvious lesions to account for the rise of temperature, the practitioner is apt to assume that he has got a case of typhcol fever to deal with. The oneone of typhoid, however, is usually insidious, and a period of prostration precedes the pyrexia. It is so in some other diseases. It is so in nearly all diseases marked by a period of incubation, though not in all; for a child may be exposed to the infection of searlet fever, and feel quite well till a sudden rise of temperature comes on. Thus, I have known a child convalescent from posumonia with a normal temperature at 9 a.u., get a rise of four degrees at 1 z.u., and forthwith symptoms of searlet fever to be developed, passing regularly through each succeeding stage. The premonitory symptoms of typhoid fever are not sufficiently well marked to enable us always to forefull what is in store for us. The absence of one symptom alone may be embarrassing, because it renders incomplete the chain of evidence we require to establish our diagnosis-there is a missing link. We have often to wait for some days, say eight or ten, till fever-spots have appeared, or there is such a combination of symptoms, as elevation of temperature, quick pulse, diarrhom, and tympanites, which leave no doubt as to the nature of the case. Whereas, on the other hand, acute indigestion is essentially a very acute disease; the rise of temperature, of pulse and respiration, being exceedingly rapid in young subjects. This very rapidity in itself should put the practitioner on his guard; such rapid rise in temperature, pulse, and respiration, is very rarely seen except in catarrhal conditions attacking children of highly pervous temperament. In these children the different pervous centres are highly mobile and unstable, and great perturbations are readily excited by slight provoking causes. To this subject we will refer further on. The same holds good of rapid variations in the pulse. A very rapid pulse quickly produced is suggestive rather of a fright or start than of any actual lesion. What has been said of the temperature and pulse holds good of the respiration, but a great inequality between the two is of ill omen, a rapid pulse with slow respiration denoting a grave condition. I may here observe that children in whom the neurosal temperament is highly marked are exceedingly linkle to disturbances in their health, and to fluctuations in temperature. I may quote one instance among many. A child is excitable, nervous, and weak; one of those restless children that are never still. It contracts a slight catarrh, and the only physical sign of the mischief is a little alteration in the breathing; but dulness is nowhere to be detected. Any agitation excites cough of a spasmodic or irritable character, and sleep is restless and disturbed. The pulse is quick, the respiration harried, the countenance is placed; the temperature in the evening rans up to 101° or more, and falls in the morning, perhaps for a few days, to 101° or 100°, and then resumes its normal state. If the child so attacked was not of this neurosal constitution, slight catarrh would not send up the temperature in this way, or manifestly affect the constitution. I have known several instances of this in rickety and feeble children who have been allowed to got into an exhausted condition. In such children the temperature may be persistently high for days together; the pulse 160, and respirations 60 to 80. Yet there have been no physical signs to account for it, no cough, no vomiting, no stupor. General tuberculosis is sometimes at the root of this condition, but in other cases the health gradually improves and the symptoms pass off."

^{4 &}quot;The physicism is liable to be mided by pluring too much reliance on the place nomina of impersions. They are not independed interiered with by complications.

We have other instances of soute diseases in children, as severe poin from abdominal trouble, colle, gravel, etc.,—a degree of pain which may even produce shock and unconsciousness.

Acute headache is very ominous in a young child, and may be the commencement of meningitis or convolsions, or precede pren-

monia, or some cruptive disease.

Collapse is an soute condition brought about by the less of blood or violent exertion, by intense mental excitement, by overpowering heat, by acute diarrhea, by the excessive use of stimulants, and by the continuance of bronchitis or pneumonia, which has so affected the nervous centres and the eardine gangila as to almost paralyze them, and to inferfere or even arrest the normal changes in the lungs. In the latter condition I have known the cerebral circulation so damaged as to lead to convulsions and death.

When a large quantity of blood is lost by homorrhage, the heart is almost paralyzed in its movements from the withdrawal of its normal stimulus, and it can only propel, at each contraction, a small portion of blood—not enough to sustain the vital functions.

Asphyzio, again, may be classed as an acute condition; it is a common mode of death in many discuses, as in baryoptomus strictulus, crossp, and in branchespursamonic, in which pus and mucus may fill up the small branches of the air tubes and cells, so that the respiration fails and the heart ceases to beat. In the latter condition we have recourse to positicing, and the free administration of attinulants to raise the faitering circulation. It may also be induced by drinking boiling water from a kettle, or from getting a head or button into the traches.

Again, in hamorrhage, which may be active or due to acute disease, when arising from the rapture of an artery as in the lung,

and accidental events. As an illustration, a young girl had passed through typhoid from countercore being declared in connection with other symptoms, by the laws of theramounty belonging to the decline of force or deformancetry belonging to the decline of force or deformancetry belonging to the decline of force or deformancetry in this disease. Suddenly heaterical symptoms were manifested, and the temperature rose to 100°. The physician, a man of learning and larger experience, so naturally alarmed. In a few hours, luveryer, the temperature declined, and property took place without further impediment. The expressive comment made by the physician was, "This is not the first time I have been fooled by temperature?" With pagard to the information forwished by the theramounter, as sold as other diagnostic symptoms, it is to be forms in mind that there are exceptions to rules which are generally applicable."—Attents Fatter. The temperature may be suited, like the respiration or the pulse, by excitations or narrownesses, especially in delicate girls or young children of mobile temperatures.

the quality of the blood gramated and the symptoms induced are quite different from the passive form of hemorrhage, which sometimes takes place from the stomach and lowels, or from the kidneys where the blood has become thin and disorganized by some poison, as that of typhoid fever; it is a state allied to congestion in its early stages, when the smaller vessels become large and rupture through long-standing debility, or some impediment to the pulmonary circulation in consequence of heart disease. For the management of this setive form of hemorrhage, value sperients, low dist, tartarated antimony, and the most absolute rest are needed; whilst in passive hemorrhage we should have recourse to the mineral acids, tannic or guille acid, or even astringent forms of iron.

Toolwest of Arriv Discost.—The chief point is to arrest it as quickly as possible, so that it may not run into a chronic form; and this may often be attained when the case comes under treatment early, and the constitution is sound. Hence we may sometimes cut short neute discuss in the young when we cannot do so in the old, because in the latter, there is not only the constitutional debility belonging to advancing ago, but tissue change also. The remedies we employ are as a rule (at least at an early stage) antiphlogistic and eliminative, such as renesection, and the use of calomel and antimony. In the violent pain of scute disease, as enteritis or colle, larger doses of option have been along any sufficiency as soon as the pain ceases.

To approach a young child in scate disease is a difficult matter, and requires much care and tact, unless it is so ill that its sensibilities are blusted, and it takes no notice of anything that is going en. To examine it, to feel the pulse, to listen to the class, or to look into the throat, are wellnigh impossible in some cases, and the information so guined is at each a cost that it is scarcely worth possessing. The fretfulness and psevishness of some children in most trying to contend with in source cases. The children put themselves in such a temper by obstimite refusal to take medicine, that in cases where coercion has to be used, it is as a rule better to abundon the medicine, at least for a time.

With regard to the use of alcohol in scute disease, perhaps there is no one point of greater importance than this. Many acute affectious in young children may be conducted safely through each stage without any necessity for its administration. If there is

cerebral exhaustion through failing circulation, it may have the
effect of stimulating the cerebral relia, in fact, of sending more
blood to the leain, and thus tranquillizing the system and promoting
sleep. If, however, there is great exhaustion, and the stounch is
irritable, and cannot retain food, gas is often generated and distension takes place, which interferes with cardiac movement. Now,
absolut under some circumstances is clearly indicated, as when
there is great excitability and restlessness, high temperature, rapid
pulse and respiration. Here a full dose of alcohol will of an produce the most beneficial effect. It is as useful here as the chronic
use of it in imperfect nutrition is to be deprecated.

In the treatment of acute disease we ought not to traverse but to follow Nature's processes. A great deal may, however, be done to expedite the different stages of the mulady. In neute indigestion, for instance, where the child vemits and subsequently is purged, the attack usually tream off quickly. Where these procome are not spontaneously instituted, we can usually do much good by administering an emetic, with a grain or two of caloned, followed in two or three hours by several grains of jalap or stansmony, according to the age and strength of the child. Also in acute catarrh, a dose of iperacuanha wine with a few drops of antimental wine will often shorten the whole attack; not only as to the first stage of vascular targessence and dryness of the broughtal lining membrane, but also that of the secondary stage of free secretion and expectoration, especially if the measures appropriate to that stage are then reserted to. These measures are stimulant expectorants and tonics. Probably inhalations of steam, simple or medicated, will tend to shorten both stages. In diarrhun, due to irritant material in the bowel which the system is itself attempting to remore, but without success, a few grains of rhabarb by its first action as a purgative will effectually dislodge the irritant matter; while its secondary action as an astringent tends to prevent any persisting diarrhous so set up.

Chronic disease may take on an acute form; it may assume acute manifestations, and it should be our aim, if possible, to prevent this. The tendency of this condition is to produce slow degenerative changes, and death from failure of the vital powers. In chronic affections after searlet fever and nephritis, scate symptoms may spring up indicating pericarditie or plearity. Bronchitis, again, of an acute and sometimes of a subscute character, frequently comes on in the strumous or syphilitic diathesis. Strumous children are liable to suffer from acute apparation of their cervical glands, or mischief in their joints, or affections of their boxes. It is often set up by an acute malady, or by a period of insufficient food. In congenital syphilis, condylomata or syphilides may be excited by some interchirent cause, notably vaccination, or even shock. Both in syphilis and strume we may have acute periods of anomals and malautrition. Under these chromatances, if the child be exposed to the poison of specific disease it will most likely have it in a very severe form of an authente type. Or a family of children with congenital taint may be at the senside when two or three days of severe cold may be experienced; one child of the number has bronchitis or paramonia, to which it may snorumb, whilst the other children are unaffected by the changes of temperature.

Acute disease is very common at an early period of life; thus infants are often carried off by convulsious when there exists any derangement of the alimentary canal through feeble digestion, or improper food. "Defective nutrition in the early stages of life, in the nursery, unrecognized by those who have the management of children, is the probable explanation of one of the problems of practice. Healthy parents, still young, constitutionally well endowed, living under favorable social circumstances, not unfrequently have children who, although apparently healthy at first, sicken and die of phthisis and of other diseases as they grow up."

General debility or uniform depression of the bodily powers, in a shronic discuse under which acute discuse may be readily excited. In this chronic state we have, as it were, to steer a defective ship through a tempestnous sea, in which it may be wrecked, unless great skill and judgment are exercised in its management.

Chronic disease is exceedingly fatal in more than one way, for either imperfect nutrition of tissues having begun, the disease goes on without the prospect of requir for an indefinite period, and during this time an neute disorder is very likely to be awakened; or if not, antrition gradually fails, and death takes place source or later from exhaustion. After death, pathological changes present themselves, which show that they must have so impaired the vital processes as to render the constitution very prone to fall before the assault of any acute disorder.

Sutrition in Health and Directo, by J. H. Berenti, M.D., 1876, p. 227.

Acute disease, then, is very apt to supervene on chronic. When the great glandular organs of the body are impaired, and the liver or kidneys are diseased, and the charination of morbid probnets is interfered with, there is in the one case the absorption of biliary elements into the blood, and in the other the retention of urinary ingredients which may deprive the patient of life, graduually or rapidly.

The effects of deficient or improper food in myiting chronic Music among children is well known, and the evidence is overwhelming on the point. The careful feeding of children is more important than their education, for if this is neglected the mental organization must suffer. If the body is not properly nourished, the brain circulation is weakened, and the intellectual powers become feelile and imperfectly developed; they do not acquire the vigor of the robust child whose digestive functions have received attention, and plenty of good food has been given at proper latervals during the day; robust children grow and thrive better, they accompash their school-work better, and they obtain more refreshing sleep. I have repeatedly seen children who are languid, weakly, and irritable, with such a history as the following: The last meal of ten and bread-and-butter is given about five or ax o'clock, they retire to bed un hour or two later, and get no other nourishment till breakfast next morning. The consequence is, that in three hours after the last meal they are drawing on their reserve, the stomach is empty, and they are so exhausted that they begin the following day quite unable to perform its duties properly. Physical and intellectual strain are both ill-borne at such times.

Deficient animal food for growing children, especially boys who follow athletic sports, is a fearful mistake; a farinaceous diet will not supply its place. Too long fasting at any age produces exhaustion, irritable brain, and enfectived digestion; the appetite becomes impaired, and whon food is taken, it is repugnant and distasteful. Malnutrition having been escublished, amenia, general debility, tuberculosis, phthisis, etc., are gradually and certainly induced.

Delicate boys often refuse to cut the fat of butcher's meat, declaring that they would rather take cod-liver oil. Now cod-liver oil is not attractive to the painte, but these children can digest it when they are unequal to the assimilation of the other suimal fats.

Treatment of Chessic Diame. This is altogether different from that of the sente form. The method is to be watchful; the sentinel has to give notice of an attack, rather than to invite it. The position is one of defence. If our treatment is to be successful we must be guided to a very great extent by the character and duration of the disease, as well as the escatitution of the patient and his herolitary or acquired tendencies. In the strumous disthesis we want more irou, more lime, and more fat. In syphilis we essentially want mercury. In caclestic conditions this remedy should be combined with iron, cod liver oil, and good food. In both cases pure country air and the seaside are important. In a nervous diathosis, quiet, avoidance of excitement, and little schoolwork, are indicated. In a billions child the great point is to look to the digestive organs-not to allow more food to be taken than can be digested, or a billions seleure is certain, and consequent depression, which renders the shift susceptible to all external infinenices.

Some remedies seem to bring diseases quickly to an end, notably in chronic disease; they arrest it, and prevent the next stage of tissue change. In this way we can care ague by quintne and arsenic; certain akin affections, as itch, by subphur; and syphilis by moreory; but the same principle does not hold good in the acute diseases, which terminate of themselves in recovery. Thus we do not actually cure typhoid fever or the exanthemata; we can watch the different stages of the special malady, and semetimes even prevent complications, or render them midder; but we do not actually cure the disease. By not being sight of this great principle we may often modify and render milder a disease which might otherwise be virulent and fatal.

How important it is that in many cheese affections the child should sleep thoroughly so as to get plenty of rest, the value of which cannot be excressionated. "The value of rest and placidity in festering the generation of that highly organized animal tissue which forms so large a portion of our staple food is well known to the stockkeeper and grazier. A homely illustration may be found in the fact, that in infancy the child who sleeps much mostly thrives; and souted souteness, the observation is equally true, that the wakeful, restless child, sedom displays the oridence of netive nutrition; and, doubtless, all will admit that in infancy derelopment is in its highest state of activity, and that the healthy infant passes the greater portion of its life in a state of rest and sleep. Growth—the renewal of some parts, and the fresh development of others, seems thus to claim as its helpmates aloop and rest."

A good physical development is the first thing to be aimed at. The quick, bright, intelligent, but slight town child, the delight of its parents and their friends, does not possess the potentialities of the strong, bulky, slow-witted, often loutish-looking child, we see in the country. The one is cuting its cake, is living its life, the other is storing up force. Slow, apparently indeed dilatory, comes the intellectual development of the typical country child; but its potentialities are far beyond those of the other child. In Westmoreland this fact of slow development is recognized in the saying that "Westmoreland hals have no sense till they are twenty-one."

There is a direct antagonism between mental precocity and physical growth. With these facts before us it is quite shar that where we have bright, quick town children, with a defective physique, a small thorax, and a flat abdomen, it becomes emineatly desirable to develop a totally different condition. No matfor at what rost to their immediate prospects these children should be sent into the country to grow into healthy animals. The more marked the characteristics of town birth, the more necessary is it to adopt such a plan. If permanent life in the country for several years is not attainable, a month in spring, and two or better three months in autumn, should be spent in the country. The duller, the quieter, the less exciting the country residence the better for strumous children. For very delicate children, it may be advisable for the spring months to select a warm and comparatively low-lying sea-residence. In the autumn, however, it is well to choose a place where the air is bracing, if by the seaside, where there are downs; in the country, where there are hills. The more nearly the life then led approaches that of the ordinary country child the better. After a substantial breakfast the children should be sent out for a walk; if at the senside, where they must take a hath, this walk should not be too long, so as not to exhaust

On Pain and the Therapeutic Influence of Michanical and Physiological Rest, soc., by J. Hillan, F.R.S., The Laurest, 1990, vol. 8, p. 193.

them before taking it. A child should never take a bath in the sea in a condition at all approaching exhaustion. If an inland residence is preferred, the walk may be made longer, provided it does not go to the length of fatigue and less of appetite. The midday meal should be substantial, and there is no objection to a sleep after it, especially if the child feels drowsy. A prejudice prevails against sleeping in the day, which is by some persons carried to extremes. The intention is that the child shall eat, sleep, and grow. If such treatment of town children were more thoroughly carried out, we should hear less of imperfect physiques, of an early breakdown after much precociousness; and town children would, so treated, approach more closely to those reared in the country. Precocity is emimently undesirable, and, if possible, to be avoided.

We must, too, never overlook the fact, that acute and chronic disease with their complications, depend upon a variety of influences and associations. The anatomical relations may guide functional complications, and even determine lesions of structure. The scrofulous, the rheumatic, and the anamic states, severally influence the liability of certain organs to suffer in different ways, because the state of the secretions, the degree of vascularity, and the morbid changes of the blood, dispose to diseased action. Vital resistance is as great in the strong as it is defective in the delicate.

CHAPTER IV.

DESCRIPTION.

Definition—Symptoms and treatment—Linking it find to aspectic disease.

Ustors the head of debility in children, or constitutional depression, I shall enumerate a group of symptoms which is very commonly met with, especially among the out-patients of our hospitals. It is a condition sometimes the forerunner of disease, and then the signs which characterize this altered health are lost in the disease which springs up. I think I am justified in attributing importance to this condition, under the title or designation of delality; for promptly recognized, it assists us to attach significance and weight to the surfact indications of a departure from the normal standard of health.

By debility, I mean functional impairment, atony, weakness, or preternatural slowness in the performance or working of the vital processes, leading, when neglected or overlooked, to debility (and it may be to structural change) in one or more of the great central organs of life or tissues of the body. This may be considered by some as involving an unnecessary addition to our medical nonenclature; but debility or weakness, as commonly employed, is used to indicate symptoms attendant on various disease, and has no isolated and individual recognition that seems to me commensurate with its importance.

The loss of blood, or free purgation, or deficient food, or any causes that reduce the vital powers of the patient, will induce debility in a simple and uncomplicated form—a deviation from that equalized condition of all the bodily and mental functions we term health. As the mustitution tardily recovers from the shock it has sustained the functions of the vital organs are sluggishly carried on, and if repair is not uniform in all of them, the balance is disturbed, and after some hesitancy disease breaks out where we least expected it. In our early contact with some forms of illness we are analyse to make any other diagnosis than that of debility.

When symptoms referable to one organ more than to another become apparent, we leave a general plan of treatment for that which is determined of the prevailing symptoms. When it has reached this stage or change, the debility I am attempting to describe has no longer an independent existence.

I claim for this a separate and special classification among the ailments of children, where debility is observed in its purest and namualized form, before degenerative lesions are common, as in after life, to account for failing strength, increasing debility, and structural alteration.

There are very well-defined symptoms belonging to this state, allike in many instances, and varying in extent and sharacter in others, the debility being a marked feature of the complaint throughout. There is powerlessness and lassitude of the whole system; every function may be said to have received a shock; a temporary pause in the uniform working of the bodily functions has taken place. The child does not usually complain of anything,

but langs and droops about, and ceases to take an interest in his amusements. The vivneity of childhood has departed; in some cases he has a shy and timid look, is afraid of your approach, and cries without provocation. In most cases there is neither discomfort nor pain; the lowels are said to be regular, but the evacuations are seamy from the small amount of food that is taken. On inquiry we shall generally find that the bowels not sometimes every day, and sometimes cace in two or three days. Among private patients, where there is no difficulty in testing the statement, I have been led to regard the latter period as the most common. The tengue is clean and moist, it may be pallid, but indicates no active disturbance. Very frequently there is a film on the tengue of a thin silvery whiteness, or the coating is thicker and yellowish, but the front of the tongue is never involved, the tip and sides showing a natural bue. Sometimes it presents a smooth and dusky aspect, as we might expect in a languid state of the sirculation. The pulse is weak, small, and usually slow; sometimes it is rather accelerated, has this is owing to the agitation and nervous excitement so readily induced by the examination. The thermometer indicates no elevation in temperature. On the other hand the skin often feels very cool, and the mother tells you that her child does not take sufficient exercise to keep him warm. He is often noticed to be being across a chair or sofa in a passive state of indifference, dropping off into a calm, quiet, and prolonged sleep. It is the quiet sleep of fatigue, and not the restless sleep of exhaustion. If awakened he readily falls off to sleep again, and is glad to go to led early, when the same drower sleep returns and lasts till morning.

In April, 1869, a lady brought to me her little girl, four years of age, who was a very intelligent and pleasing child. I was left to find out her altment as well as I could, her mother saying "she really did not know what was the matter with her, but sie was certain she was not well." When a year old the child suffered from pulpitation, and two years afterwards she had whooping-cough. She appeared well till eight weeks before I saw her, since which time she had been siling in health. She was said to be "very languid, constantly yauning, and wishing to go to bed early in the day." Her face flushed on being asked a question, and when a stethoscope was applied to her chest she burst into a fit of tears, which her mother said was not untural to her; the tongue

DEBILITY. 65

was furred at the back, and the urine was rather high-colored; the lower cyclids were slark, and the expression languid, but no complaint winterer was made of pain; the lowels were rather confined. I advised that the child should be tempted to take nourishment frequently, milk and eggs being given in the way that were most agreeable to her. She was not to suffer fatigue from running about, but to be driven in an open carriage when the weather was fine, or to be wheeled about the garden. Aperient medicine was strictly forbidden. Thirty minims of the Syr. Ferri Phosp. Comp. in two tenspoonfuls of water were ordered three times a day. Improvement soon set in, and on the 12th of May she had nearly recovered her usual activity, the appetite had returned, the tongue was quite clean, and the bowels acted regularly every day.

A careful physical examination in these cases rereals nothing important about the chest or abdomen. The two most common attendant symptoms are beadache and poin at the epigastrium, both being signs of debility in the brain and stomach respectively. So far as we can learn, the headache seems to be a heavy oppressive weight across the centre of the forehead, and it is very pereistent, giving the child a doll and painful appearance. In many of these cases the aspect is desponding and immimute, and the cheerful expression of childhood has vanished; the eyes are heavy and have a hollow look, but there is nothing approaching intolerance of light, nor squinting, as we observe in threatening cerebral disease, though it is not to be forgotten that the brain may be involved if these symptoms are allowed to go on without treatment. The pain in the stomarh is of the same dull aching character, rather discomfort than actual pain, and is limited to the root of the ensiform cartilage or its immediate vicinity. It is the uneasiness of slight gustralgia, or the guawing sensation we have all experienced when the stomach is empty, and we are waiting for a meal to appears it.

There may be aching of the limbs, muscular fatigue, and pain

in the course of the spine.

The sympathetic system shares in the general constitutional depression, and is reduced below its normal standard. The appetite required to insure the perfect digestion and assimilation of food and nourishment is impaired, and the emotions are susceptible and beightened to a degree which readily excites disturbance of both mind and body. The face may change from the pallor it exhibits in repose, to frequent blushing, and there may be polpitation of the heart, all induced by slight correction or fatigue, or the overtaxing of the digestive functions even with the ordinary diet of health, when half paralyzed by fear or emotional excitement.

There is no very striking symptom which indicates this derangement in the health. It is to the totality of them we must look for a diagnosis. This must be arrived at by a careful process of exclusion. The indications of the disease are negative, and it is the fallors in the discovery of any specific cause for the defellity which indicates its pure and uncomplicated character. There is nothing, so to speak, that is apparent or tangible, and hence it is that a deprayed state of health creeps on annoticed, and is not discovered till some very prominent symptom arrests attention. There is no cardiac affection.

Such cases as these make us cautious in giving an opinion. In the absence of any discoverable disease, we are doubtful whether this unaccountable delility may not to the harbinger of mischief to start up hereafter. Disease may be hidden, to come forth by and by. In the diseases of adult life, a cause is often discovered. Not so in the cases I am describing; the debility is uncomplicated, and it must be seen and treated before it has merged into notual disease.

These cases usually terminate well if promptly and skilfully treated, but a continuance of this condition may lead to protracted disease, and subsequently to death. For example, deficient nervous power, as shown by headache, may lead to cerebral exhaustion, and to come and convulsions, in the same manner that congestion and inflammation of the brain may terminate. These are opposite states of the system, leading to the same consequences, but requiring a different mode of management.

The weak and enfectled stomach of young children, causing instant rejection of food by veniting, is often checked by a simple stonic, and sympathy is so strong with the cerebral functions, that when the stomach has recovered its power, the brain is inflet into quietude. If it did not so yield to treatment, the symptoms would pass on and implicate the brain in the manner just described. To equalize all the forces of the body is the surest method of maintaining its efficient working. It is the loss in either that invites discuss.

When the debility has weakened the digestive and nervous functions, and induced loss of appetite, muscular pains, deficient and high-colored urine, and torpid bowels, a plan of treatment the opposite of that which is stimulating and generous, may suffice to bring about a return of strength and animated feeling.

These eases of pure and simple debility, when neglected, cause chores, epilepsy, convulsions, paralysis, etc., and finally lead to those changes in the blood which originate ansunia, tuberculosis, and every form of diathesis that lowers health and provokes disease.

CHAPTER V.

DESTIIIOS.

Seminates: In leading relations there is after an advance of suffering. In the righty and thiroto, adults and or corried discuss may appropriate. Temporary and permutation that — Order of their appropriate — Discribes — Consolium — Encounting of the also. Curves on Discribes — Discribes. The righty sometimize — Function. Transverse: Depends upon the through and constitution.—The strong and vigorous to be tracked differently from the fields and righty.—Appropriate — Commencing, burnish and solide of posteriors, hydrate of oblives — Lunning the game.—Care in dist.

Duxtrates is a subject which requires careful consideration, for it is important that we should form definite ideas concerning the part it plays in affecting the health and exciting convulsive and other diseases. Whilst the dangers of dentition have undoubtedly been exaggerated by some authorities, and the friends of the child are apt to become anxious during this period, there is, it must be remembered, a real degree of risk in certain temperaments. Every thoughtful practitioner ought to be on the watch for indications of disease, which the process of teething is capable of exciting.

In perfectly healthy children the teeth appear one by one in regular succession with little or scarcely my suffering; in other instances, as in the rickety, their advent is contemporaneous with the commencement of delicate leadth; and in another class they are the lurbingers of abdominal or cerebral mischief. The evolution of the teeth tests the vigor of the child, and the more tardy and lingering the process, the less is its strength and vitality.

The teeth begin to appear in healthy children between the seventh and eighth month, and the process is completed between the twenty-fourth and thirtieth mouth." The two middle or central incisors in the lower law first appear; then in the course of a week or two the two middle incisors in the upper jaw; next come in another month or six weeks the two lateral incisors in the upper law, followed by the two lateral incisors in the lower jaw. Then about the twelfth or fourteenth month the first four moints appear, generally those of the lower jaw first; but they do not follow any definite order in their appearance. After the lapse of another three or four months the four canine teath suceced, and between the twentieth and thirtieth month the four posterior nedars pierce the gum, thus completing the number of twenty-four teeth. These are called temperary teeth. The permozen' teeth are thirty-two in number, and they make their appearance as the former are shed.

The personnel teeth belong to that important period of childhood—the sound dentition. These teeth begin to appear between the seventh and eighth year, and at this time there are fortyeight, twenty decidnous, or perfectly developed teeth, and twentyeight permanent teeth in various stages of development. The evolution of the first true molars is, according to Mr. Saunders, an evidence that the child has attained the age of seven years.

The following table is of assistance:

Central incison developed at 8 years.
Lateral incisors 3 "
First birmepid 10 "
Second birmepid 11 "
Cantage 12 to 12) years.
Second malaret 12 to 14 "

[&]quot;If a whild pass over the winth searth without north, you should corriedly impaire
for the cause. It may be that an asure illness has recarded deptition. It may be that
that is very rare, that there is some condition of the gran which inverferes with the
alcaner of the teeth. It may be (and this is infinitely the most common cause of late
deuthion) that the child is rickety: fail not then, when railed to a child in whom the
teeth are late in appearing, as look if it be rickety, for, if you do fail to look for rickets,
you will most likely attribute to the invitation of teething symptoms which are the
consequence of the rickety distless—the has deutified in rickets being in itself mostly
a symptom of the general disorder. The rickety deformatios may be very triffing, and
you the costs considerably retarded in their development."—Lestons on Evilon, by Six
William Jeener, Bart., M.D. Medical Times and Garotte, vol. i. p. 334.

[†] Carpenter's Physiology, 8th edit, p. 1106.

Symptoms.-The symptoms and disorders that accompany the first dentition vary in different cases. A perfectly healthy child may not suffer in the bust degree, one tooth appearing after another without causing any local or general disturbance; but, in many instances the excitement is considerable; the mouth is bot and swollen; the cheeks are flushed; the child is fretful and sleepless; it resents the slightest interference; the appetite fails; thirst is present, and often sickness and diarrhun as well. One of the earliest symptoms attending dentition is an increase in the activity of the salivary glands, and saliva is seen to be constantly drivelling from the mouth; but this naisture may be present for some weeks before the teeth appear. In some cases the constitutional disturbance is even greater than that which I have described; the mouth is but and dry; aphthous alteration is seen on the gums and inside of the chooks; the tongue is thickly ecated, and the child can no longer snek. Convulsions and spasmodic movements are very common in teething children. Frequent contractions of the muscles of the eyes, the lids of which are only partially closed, and the eyes turning upwards beneath the upper cyclids, so that the white selerotic is only seen, give a terrified expression, and is alarming to the parents. Rolling of the head, twitching of the facial muscles and of the limbs, flexion of the toes and fingers, and a peculiar smile are often observable at such a time. In this state of excitement almost any sympathetic disorder may spring up, as bronchitis, convulsions, meningitis, diarrhosa, and ecsematous and crythematous affections of the skin. Some of these affections are quickly fatal, and others tedious and difficult of cure. In rickety children deutition is delayed. They are feeble in constitution, the appetite is expricious, sleep is disturbed, and the bowels are relaxed.

During dentition, children are very liable to diarrhese, the muccus membrane of the bowels is irritable and sensitive, and if the food given is not easy of digestion, or if the weather be cold, it is easily induced. What share teething exerts in causing diarrhom it is impossible to say; but there is a close connection existing between these states. When diarrhom is present we do not hastily attempt to check it if the teeth are piercing the gums, and the month is uneasy; still, if the drain continues or is excessive the child becomes exhausted, and the possibility of convulsions must not be overlooked. Distributed may be in some measure due to enfeabled digestion caused by pain and restlessment, and general disorder of the system. Billard attributed it to an increased development of the intestinal follows and glands, which is noticed at the period of dentition.* A year of delicate health may elapse before a tooth is seen, and then one may slowly appear without causing pain. Convulsions in a case under my care preceded the appearance of each tooth.

Children who suffer from difficult dentition will be often observed to roll the head from side to able, and to raise the hand to it, or put the fingers in the mouth. Sickness and febrile disturbance are noticeable; the child becomes languid and wastes, the muscles are flabby and the joints relaxed, the motions are offensive, and dark, green, or slimy. Slight ulcerations of the mouth are common, the child is prevish and irritable, it experiences pain

on taking food, and does not obtain sound sleep.

In some rickety children during dentition, sickness and vomiting are the chief symptoms, and the child is drowsy and inclined to sloop at any time during the day. If the bend is hot, and the veins distended about the scalp, the pulse quick, and the temperature runs up to 101° or 102°, we may with reason dread the supervention of convulsions or meningitis. Convulsions in several children of the same family are often to be met with. In one instance a mother had but three children from convulsions during dentition; the fourth shild was the subject of laryngismus stridulus, and at two years old it had only seven teeth. Laryngismus stridulus frequently attends dentition in rickety children, the science passing off as the teeth appear, and the general condition improves. Eruptions on the face and scalp have been usually attributed to dentition—the "tooth-rash" of vulgar talk.

The course of difficult and delayed dentition are an acute discase, the rickety constitution, strums, marasmus, and tuberculosis. All these disorders retard the development of the teeth, by

lowering the general health.

In some cases we may trace the failure of health from the times of vaccination when it is performed at the third or fourth meath; this in many instances seriously interferes with the development of the teeth, and disposes to reflex nervous irritation.

The mortality under the age of two years has been variously

On the Dangers of Destition, by J. Finkeyson, M.D., Obstetried Journal, 1812-74, p. 591.

estimated by different writers, some ascribing half the deaths, others a third, and others again, a sixth, as due to difficult death-tion.

The treatment of dentition will depend upon the general symptones that are present, and the constitution of the putient. The practitioner must exercise his own judgment as to the treatment be will adopt, and not blindly attach himself to any routine plan. The strong and vigorous child who is feverish and thirsty, with a hot and tender gum, a full pulse, and constipated bowels, will demand quite a different mode of management from a puny and rickety child whose teeth are delayed. In strong children a grain of calomel with two or three grains of rhubarb will be required to clear the bourds. A saline mixture, as the citrate of potash, should be given to abute the pyrexia, and if the child is excited and sleepless, a few drops of tineture of henbane may be added, or a draught at bedtime containing hydrate of chloral and bromide of potassium, should be given. The child's head should be kept cool, and whatever determines to cerebral congestion should if possible be prevented. "Affusious of the head with cold water, performed every hour or two, are, it is true, a not very tender, and by parents not much admired, remedy; it is, however, very useful against all convulsions in children, and therefore against those occurring during dentition."+

In the rickety, a mild aperient is occasionally required, such as blearbonate of soda and rhubarb, to regulate the bowels, and to correct the secretions. A tenspoonful of castor oil may be advisable now and then, and if the bowels are over active, a grain of Dover's powder at Isoltime is often of great service. If there is somiting and flatulence some carminative will be necessary. A mixture containing hydrocyanic acid with solution of magnesia and sal volutile often answers exceedingly well.) In cases where there is much restlessness and disturbance of the nervous system,

^{*} Vegel, Dissess of Children, 1874, p. 106.

B. Arist Hydrocy, Dil., Sp. Spt. Arism. Arism. Stropi. Stropi.

To be taken every four hours,

bromide and iodide of potassium with sal volatile will often abate

sickness, and rolleys head-symptoms if present."

The gam lexest is occasionally required. If the tooth is nearly through, but still hidden, and the gum is red and tightly stretched over the tooth, then a proper incision will give much ease, and the slight bleeding will relieve the capillary vessels. It is both mischievens and cruel to have recourse to the practice if dentition is going on naturally. This practice of lancing the gums is a very old one. It appears inconsistent with the state of medicine in the present day to suppose that puncturing the gums would be so frequently resorted to if it had no advantages. "May not some diseases be rendered milder, and their favorable termination more certain or probable by measures calculated to relieve the turgescence of the gums? If so, these who totally disregard the state of the gums, are not less in error than those who use the gumlancet when it is not required."t The cases where incision is required are probably few, but there are undoubtedly some which do benefit by the operation, and where convulsions have been provented by having recourse to it. When the gum has yielded to the advancing tooth a child often experiences instant relief and comfort. So far from causing the infant pain, I have repeatedly lanced the gum without the child evincing the slightest indication of feeling pain from it, but of obtaining speedy relief. I have never seen hamorriage or elegration of the gums follow, and in properly selected cases it certainly has its advantages.

Finally, care in diet is of the greatest importance whilst a child is teething. Improper food will easily bring on acute indigention and febrile excitement, demanding the use of salines and aperients

till the system is again tranquil.

CHAPTER VI.

MARASSUS OR ATROPHY.

Soirer and definition of —Deficient food the most manness cause—Martality among infrares

—In treatment the personny object to to remove the conne—Clare in feeding—Cod-Lowod—Bern ment joire—Deficient formants—Légaie Poplace and Legaie Personations —Soires remove of payme and personnils—Lead physical of popula—Artificial departure.

Armoray consists in the decrease of size of a tissue, or of the whole body, with consequent impairment of function. It is the opposite state to that known as hypertrophy. When adipose tissue atrophies, the fat-cells diminish in size, owing to the gradual loss of their contents, and smaciation results. The elementary constituents of any other tissue, or organ, or set of organs may become similarly affected, and so produce diminution in size, and a proportionate impairment of function. It is not the same process as degeneration, although degeneration is always sooner or later accompanied by atrophy. Degeneration consists in the deterioration of the quality of a tissue, and does not (at all events at first) necessarily imply diminution in its size. On the contrary, the size may be temporarily increased, as, for instance, in fatty degeneration of the liver.

Atrophy is a common disease among infants and young children, as the out-patient practice of any London hospital amply testifies. It has its origin in defective nutrition, and is rather to be regarded as a state of extreme debility and lowered vitality than as a specific and independent affection.

"Experience has taught us that patients often die without offering, in the post-mortem examination, the slightest modification in the anatomical condition of their organs. In the course of our physiological experiments, we often see dogs arrived at the very last stage of emariation, although the appetite continues unimpaired till the last moment. They sink from sheer exhaustion, while the lasteals are gorged with chyle; and, when opened, their bodies offer no trace whatever of pathological alteration."

Conses.—Whatever interferes with the autrition of an organ is followed by its atrophy. If the food given to an infant be un-

^{*} Levere or Experimental Pathology, by Claude St. Fernand, Medical Times and Garette, 1800, col. 5, p. 200.

wholesome or deficient, the digestive organs are somer or later deranged, and the processes of assimilation are disturbed. The autritive changes in growing tissues are far more active than in the mature; consequently any interference with the nutrition of an infant is followed by far more rapid and serious consequences than in the case of an adult.

It has been pointed out by Dr. Murchison that emaciation may arise from functional derangement of the liver, as when the hile is impeded in its passage into the bowel, and the assimilation of fatty and albuminous matters is interfered with, or from dirangement of the glycogenetic function of the liver." It may also arise from stricture or obliteration of the thoracic duet; by which means the chyle elaborated by the mescateric glands fails to reach the general circulation. Atrophy is also caused by whatever occasions any great waste of nutritive material. Thus, prolonged issmorthages, long-continued supporation, excessive coniting and diarrhous, by depriving the body of large quantities of nutritive matter, lead to general atrophic changes.

As to some other conver of atrophy, the most frequent are any circumstances that bring about defective putrition in infinite and very young children. A child may have been born bealthy, but the mother is suddenly unable to suckle it, and from that moment it ceases to thrive. No artificial food can effectually take the place of the mother's milk, the child wastes and becomes emariated, diarrhea and vomiting ensue, and it dies exhausted. In another class of cases the child is incessantly sick, and life is frequently arrested by an attack of convulsions. Hundreds of infants die annually in London and other large cities because the food given to them is either unwholesome, indigestible, or insufficient, their digestive organs are too feeble to assimilate it, or the mother is working hard, and in delicate health at the same time, and so has not sufficient breast-milk to nourish her infant. We continually see pale and feeble women bringing up their children by the breast when a year old, and they tell us with some surprise that since their milk diminished the children have not theiren. The blood, in these cases, gets into a thoroughly impoverished state, and the mannuary glands can no longer secrets milk sufficient in quantity, or good in quality.

^{*} Croosian Lectures in Franciscal Desagements of the Liver, The Lauret, 1874, vol. i. p. 467.

It has been pointed out that food rich in starchy products is a common cause of atrophy in young children when given to them before the salivary and pancreatic glands have reached their full development. Before the seventh or eighth month the starch is not converted into glucose or sugar, and hence one cause of indigestion and defective nutrition.*

The mortality among infants brought up by hand is enormous.†
The deaths during the first two months are four times the number
during the third month.] Where infants are imperfectly fed,
nutrition takes a wrong direction, and if they do not flag or die
early, then some morted deposit in the shape of tubercle may be
infiltrated into the different organs, or more inflammatory affection set up.

Sometimes young children, without any ascertained cause, anddealy become fretful and irritable, and lose flesh and strength; the face grows pale, and the body-heat diminishes; in these cases they sleep budly, there is uncestness in the bourds; the motions are dark and offensive, and death gradually follows.

"In shronic atrophy the last traces of adipose tissue disappear from the face; the integrament everywhere becomes loose and corrugated, and, in addition, various contractions of the muscles take place, as a result of cerebral irritation, especially that of the frontal, next of the corrugator supercilii, and the levator also nasi et labil superioris muscles, by which the face acquires a scalle appearance, and, on account of which, the French Pacliatricars, in a very negaliant manner, call it a Voltairean face."

^{*} See Chapter IL.

^{1.&}quot; In England, out of 100 children born; while for the whole period of one year 15.2 per cent, children will die the first receib, 1.7 the rest, and receib, 10 Ferrare, out of a suffice highly, 29,123 die is the first week, 22,128 in the second, and 22,256 in the second, and 22,256 in the second over following." On Johnst Fredrich by C. H. P. Routh, M.D., 1876 p. 64.

^{2.} According to the English Life-Table, of 1,000,000 children bern, 140,401 disbefore they reach the upon of one year; and of these 141,483 deaths, 40,503, so mostly a third, die during the first month of life. The annual rate of countries per 1000 among inferior, occurring to this English Life-Table, is equal to 171,2 in the first would of life; duclining, however, to 91.6 per 1000 in the alcount month. The annual rate among inferior upon one month and under one year does not exceed 111.6 per 1000; whereas among intents from birth to one year of age it is equal to 165.6. In its evident that in dealing with the mornility among infants during the limit year of life it is accounty to take account of the age in months at insurance, for the rate of mortality among infants aged six moreths is but one-lifth of the rate which prevails during the first smalls of 160. — Infant Jamesons and Morethy, Brit. Med. Journal, vol. 1, 1905, p. 785.

Vopel, Diseases of Children, 1874, p. 15.

In the tensional of Managers and Atophy we must neek to remove whatever influences appear to have induced the disorder. If the mother has not milk enough to support her infant, a wetnurse should be procured, or it must be brought up by hand, and every care ought to be bestored on feeding, according to the age and digestive capabilities of the child. Into this question I have already entered.* Cod-liver oil may be given to young infants after food in these cases, with the greatest advantage; it will have the effect of improving the appetite, promoting sleep, correcting the secretions, and increasing weight. When it does good, sick-ness is not induced; indeed, I have seen many infants cease to be sick on taking the oil. Half a tempoonful of steel wine may be added to the cel in suitable cases. If end-liver oil cannot be borne an equal quantity of glyceria may be given with good results. It is usually taken with relish. Insunction of cod-liver oil is also of service. Bus west juice in some cases of atrophy and wanting proves highly antritious and digestible. The directions for preparing it are given in another place?

Cases will sometimes occur in which the digestive functions are completely in abeyance. All foods are rejected by the stomach or passed undigested by the bound. In such cases so these, as indeed, in all where the alimentary truct is in a high degree of irritation, the principle of physiological rest will be found to be of great value. We must give the digestire organs as little to do as possible; as they cannot perform their functions effectually, we must relieve them of this, by introducing artificially digested food, and thus reduce their work to that of more absorption. This can be effected by "peptonizing" the food before it is given. There are several valuable preparations of the digestive ferments in the market, while many are practically inert. Amongst the most effective may be mentioned Benger's prepara-tions, the "Liquor Pepticus" and "Liquor Pancreations;" Savory and Moore's two saline essences of Pepsin and Pancreatin, Ballock's Acid Glycerin of Pepsin (which, on account of its sweetness, is readily taken by children), and others. The strength of these preparations is very similar. Dr. W. Roberts has called attention to this subject in his Lumdeian Lectures on the Dignstive Ferments. He says: "Any extract of pancreas may be used for

^{*} Son Chapter II.

the preparation of artificially digested food, but the most soitable are those prepared with dilute spirit or chloroform-water. The extract sent out by Mr. Benger, under the same of 'Liquor Puncreatieus,' is an almost faultless pharmaceutical preparation. It is made by extracting perfectly fresh and finely obopped pancrens, with four times its weight of dilute spirit. By some ingenious derices, Mr. Benger has succeeded in overcoming the mechanical difficulties of the manufacture, and has produced an extract which possesses the diastatic and proteclytic properties of the pancrens in a highly concentrated degree. It is a nearly coloriess solution, with very little tasts or smell beyond that of the spirit cool to preserve it."

The following are Dr. Roberts's methods of artificially digesting milk and milk-gruel:

"s. Perrosises Mill.—Fresh milk is diluted with water in the proportion of three parts of milk to one part of water. A pint of this mixture is heated to boiling, and then poured into a covered jug. When it has cooled down to about 140° Fahr., three teaspoonfuls ((5iii)) of the Liquor Pancreations, and twenty grains (about half a small teaspoonful) of bicarbonate of soda (in solution) are mixed therewith. The jug is then placed under a "costy" in a warm situation for one hour. At the end of this time the product is again boiled for a couple of minutes. It can then be used like

ordinary milk.

"b. Perrosizer Mills Geurl.—Half a pint of well-bolled grael is added, while still boiling bot, to half a pint of cold milk in a covered jug. The mixture will have a temperature of about 125° Fahr. The Liquor Pancreations and the bisarbonate of soda are then added in the same proportion as in the preceding process (c). The jug is placed under a 'cosey' and kept warm for an hour and a half. The contents are then boiled for a couple of minutes, and the product is ready for use. By this second method the use of the thermometer is dispensed with."

In cases of great debility and exhaustion it may become neces-

sary to feed the child per rectum.

The following is Dr. Roberts's plan of preparing nutritive enemata: "A nutritive enema should be prepared in the usual way—of milk, or of milk with beef tea or eggs, or of milk-graek.

^{*} Londoine Lectures, On the Dignetics Forments, by W. Roberts, M.D., F.R.S., The Lancet, April, 1990, to which the reader is recommended to refer for faciliar particulars.

To half a pint of the warm enema a tablespoonful of the Liquor Pancrentieus, and thirty grains of blearbonate of soda should be added. The enema can then be administered at once."

Two ounces is quite sufficient at one time, for if more be used it may not be retained.

CHAPTER VIL

PRIVERS OF CHILDROUS.

Defaction of from the course and symposium—Action of the four-points on the blood and notes in system—The mention by inition distings of critics—General menogeness of forces, populations and surveint—Simple februaris—February-February-Februaris—Februarism simyles—De disjointime, season, symposius, and teaconsent.

The term fover is employed to signify an accelerated state of the circulation, with thirst, loss of appetite, elevation of temperature, prostration of the mental and bodily powers, and derangement in the secreting functions. These changes are the consequences of external causes, which the system is unable to resist. The causes may be sudden or slow, powerful or mild; they may temperarily impede its actions, and eventuate in a speedy restoration to health; or they may induce a combination of phenomena which destroy the life of the patient.

All diseases which exhibit febrile symptoms at their commencement must have a close resemblance to one another, and do not then admit of a diagnosis, which is easy at a later period, when the development of particular symptoms enables us to fix the exact nature of the affection, and in many instances to trace its origin. Different individuals are variously affected according to peculiar circumstances, and the state of the general health at the time of attack. Thus exposure to cold and moisture in one person produces only a feeling of malaise and general constitutional disturbance; it does not fix upon any particular organ, and terminates without complication. In another person, as the general disease advances, there is a determination of the complaint to some organ; or in a third person the local disease may proceed as rapidly or even more so than the general disease may proceed as exemplified in some cases of pneumonia occurring in young and

vigorous subjects. Then there is a class of cases in which the local disorder precedes the constitutional, and the inflammatory symptoms increase and become more developed, whilst the symptomatic fever and general derangement follow later.

Increased heat and accelerated circulation constitute fever, and without them the patient cannot be said to labor under it. In the early stages they may be absent, as during the period of depression and lassitude, when the vital energies are prestrate, and before the system has shown any reaction. But quickly come remarkable changes and manifestations, as uncasiness, restlessness, shivering, coldness along the spine, involuntary tremors, rigors or convalsions, and exacerbations. And to these sucreed lesions of the organic functions, in disturbed respiration, circulation, digostion, and nutrition; the attitude is altered, the expression changed, and the intellectual powers enfeethed or destroyed. The symptoms are owing to changes in the quality and constituents of the blood, which becomes altered in color and consistence, the serum increased, and the crassamentum thickened or loosened. Then follow changes in the quality and amount of the secretions; they become patrid and offensive to the tissues in which they are in contact, and lead to local inflammations and changes of structure. The fever-poison enters the blood and paralyzes the nervous system-it affects all the solids and fluids of the body, and tends to the disturbance of its several functions. It is well that we should bear in mind the liability of the mildest form of fever to change its characters and become developed into a dangerous type at some period of its progress; and hence it is that very mild cases of typhoid (remittent) pass off in a few days, whilst in others they become severe, protracted, and even fatal. From constitutional infirmity or improper diet, alarming symptoms may arise at any period of the fever, or if the blood is surcharged with the contaminating elements of tissue metamorphosis, which the exerctory channels cannot eliminate, coma or delirium may set in unexpectolly and destroy the patient's life. Thus it becomes a trite maxim, which observation daily indorses, that "where there is fever there is danger."

All fevers have a tendency to terminate by critical change or crisis, as it has been termed, if the vital powers are not too much exhausted. This is seen in ague and some idiopathic fevers, in which a free sweating, or evacuation from the bowels, is followed by favorable symptoms.

In the management of fevers in general there are prophylactic and curative measures to be horne in mind. If the causes which produced the fever can be ascertained they should be removed, and the patient placed under the most favorable hygienic conditions, Such measures should be resorted to as support the constitutional powers and encourage the due performance of the different functions of the body. Excess of food, by inducing vascular plethora and general excitement, will predispose to fever, whilst moderate exertion of the mind and body, and the inculcation of habits which neither overexcite nor depress, will emble the child of delicate physical organization to resist the infectious effusia or other epidemic influences which strike down the robust and strong. In districts where the soil is low and heavy, and there are many trees, children should not be exposed to the night or morning air on an empty atomich, and if it can be managed their aportments should be at the top of the bouse. In the autumn season of the year an occasional dose of quinine and a mild aperient will be advisable in unbealthy localities. In short, a due regulation of the digestive and secreting functions should be observed, and all causes that morally or physically depress the system should be carefully avoided. When the impression of fever has been made, its full development may sometimes be prevented by a careful diet, rest in bod, laxative medicines, and cooling drinks; by the employment of a warm hath, or determining the blood to the external surface, Although these measures may not arrest the fever, they will control the premonitory stage, and render the subsequent disease milder and shorter in its duration. We shall treat of the serious complications that arise in the course of the specific fevers under their respective heads.

Simple febricula, or feverishness, is the term I would employ to express a slight degree of fabrile action. It may be classed as a mild grade of inflammatory or continued fever terminating in twenty-four hours, or lasting over a few days. The affection is not peculiar to children and may occur to adults. The mildest variety is generally caused by fatigue and exposure to the sun in hot weather, or by prolonged mental excitement, or by continuous study in close rooms. I have met with several lastances of this kind and almost invariably in the summer season of the year,

when the weather has suidenly changed, and become hot and relaxing. In May, 1877, three children, aged respectively five, soven, and eight years, were brought to me in the Out-patient Department of the Samaritan Hospital on the same day, with temperatures varying from 101.62 to 104.41 (rectum). May 14th .-The youngest child had the highest temperature. She had been ailing for a week, refused food, and was extremely thirsty and frotful; there was a shrill croupy cough, and the hands and body were very bot; pulse 140, respirations 50 per minute; the tongue was whitish and moist, and one or both cheeks flushed both morning and evening; there was no diarrhua, and the urine was clear. I thought the case very like typhool fever, or acute tuberculosis; rather the latter affection. I ordered half a grain of quinine in a powder with sugar night and morning, and a mixture of citrate of potash and bromide of potassium three times a day. On the 17th she was no botter, refusing beef tea and sourcely taking my milk; there was constant cough and the bowels were inclined to be loose. The temperature in the rectum was 104.2°, pulse 130, respirations 40. On admission as an in-patient two days later (19th), although no change had been made in the treatment, the temperature at 8 p.m. was 18.2", and it never exceeded 18.6" during the month she remained in the hospital. On a careful examination of the thorax some slight muccus riles were detected when the child coughed or cried, but there was no duliness anywhere. The urine was cloudy and contained phosphotes in abundance. A mixture of phosphoric acid and quinino was prescribed, and a week later the child was running about the ward, eating an ordinary diet, and left the justitution on the 16th of June quite well. the absence of local or specific disease, we must classify those cases as "simple febricala" or "pyrexia."

This fever is also the consequence of local irritation and temporary obstruction to the digestive functions. If the source of irritation resides in the stemach from an undigested neal, an emetic gets rid of the effending mass, and subdies the fever at once. If digestion has advanced to the stage of imperfect chyliteation, the separation of nutritive elements does not properly take place, and absorption of well-selected elements does not ensue; whilst there is retained in the intestinal canal matters which also become sources of irritation till an active aperient washes them out of the system. Hence the rapidity with which

this simple variety of fever departs, leaving behind it so ill effects. Worms in the intestinal ranal exercise secretion of labs, indulgence in stimulants may induce it. However simple the fever may be, it is marked by a coexistence of asymptoms, and is not characterized by any single one. It depends on a variety of exciting causes, and is not specific, nor does it present anything of a definite character like those cases of fever arising from centagion, in which there is a change in the healthy proportion of the constituents of the blood. During the period of the first dentition the infant is liable to pyrexia, which passes off with the appearance of the tooth through the distended gum; or it may have convolsions, which may depart quickly or return from time to time, and even end fatally if the pencess is slow, and the coustitution is intolerant of the irritation through excitability of the mercous system. When the fever arises from the various causes which excite gastrio or intestinal disorder, it may be called symptomatic fever, for there is neither shivering, brown tongue, nor active cerebral disturbance, which belong to the exanthemators ferers. Still caution is necessary, as severe fevers often set in with very mild symptoms. It is doubtful whether such cases ever lead to a fatal termination. The temperature from slight sources of irritation in these cases may rise to 105° Fahr, in the evening (as high as is common in truboid fever) and fall to the normal point next morning. In fact, a high temperature in children is often a delmive indication when not viewed in connection with other symptoms."

In this symptomatic fever (for I still elling to the term in the abort variety of the affection) the lassitude and general weakness are slight, because the nervous centres are not severely depressed, whereas in the specific fevers they are sometimes involved to a great extent, and the cerebral functions are destroyed or seriously in-

[&]quot;"times of ephenoral firer, without any very serious formbrides (bobartapeolist Reprinting), are passivalistic characteristic of the preson of childhood. Therefore, is childhood discusses, over when we find a very high temperature, we must be very exceled in drawing conclusions from the first (or a single) observation. At this are also more or loss high temperatures may move at stages (Paulita) in the course of a discuse, in which we generally find very moderate or normal temperatures in the adaptated with in considerate, any considerable elevations of temperature are mountains mot with in children."—Wanderlich, On Medical Thermostry, New Syd. Suc., 1971, p. 208.

volved, as when effusion takes place, or the concentration of the special poison partially or completely paralyzes them.

Treatment.-This consists in the first instance in giving cooling. drinks, and, in the shape of nutriment, nothing beyond milk and seltzer water. A few alterative doses of gray powder and rhubarb, or a brisk purge, will bring down the temperature and soon set matters right. Sometimes an emetic acts like a charm. The cause his only to be removed, and, if not long in operation, the child is quickly restored to its usual health. There is no serious congestion or irritation of any particular organ, and consequently the depumting functions are only temporarily impaired. As soon as the fever begins to decline (or before, if there is much moisture on the skin) quinine given three times a day will be found of great service. In those cases where there is a febrile puroxysm morning and evening, I am in the habit of giving quinine before it is expected to come on, and when it is fully developed I recommend a simple saline mixture, cooling drinks, and cold sponging, Where there is much cerebral excitement it is well to give the quinine in hydrobromic neid.

CHAPTER VIII.

TYPHOLD PHYEL.

Before and emission manager—before the remarked force and applied force against the series of applied force.

Supposed of typical force from montaging Arabidotechnical Symptoms appeared to the supposed force from montaging Arabidotechnical Symptoms appeared on the supposed of the force protein—Eg material Humanium.

Typhoid or enteric ferre is distinguished by the prevalence of gastric and intestinal symptoms. It has received the name of intestinal fever, pythogenic fever, and muco-enteritis. Most German writers call it abdominal typhus (typhus abdominalis). In addition to these terms, there is the well-known name of infantile remittent fever.

I must disayow at once any belief in infantile remittent fever as caused by a separate and distinct poison, or that the disease differs in its nature or causes from that of typhoid. I can conceive few greater blunders in practical medicine than to consider this a separate and distinct affection, not following the same course as typhoid fever, and not leading to the same complications. To me it seems, however, that there is a condition to which this term may be applied without rausing confusion; it should be limited to the mildest cases, which usually run a quick course, and do not develop into the severe and unmistakable typhoid.

The torm may be vague and ill defined, but it conveys to the minds of many persons a form of mild fever arising from minematic influence like typhoid, and attended with much gastro-intestinal disturbance. In these milder cases we have no characteristic rash, and the short duration of the fever in some children does not allow of its being classed under the name of a specific disease. The pyrexia is due to a depraved condition of the alimentary canal, of long or short duration, and when this is convected the disease quickly departs. To such cases as these the term typhoid fever could not with propriety be well applied.

I would not, however, mix it up with simple febrile disorder, nor with fever symptomatic of worms, dentition, and viscoral derangement, which pass away as quickly as those conditions are remedied;" but it is something more chronic and intractable, lasting only a few days in some instances, whilst in others it has the duration and all the attendant complications of the genuine typhoid state. To these milder forms, caused by the imbilition of a small dose of fever poison, I wish especially to draw attention. If we will accept the term with this understanding it cannot mislead us

In the nomenclature of diseases, drawn up by the Royal College of Physicians of London in 1869, infantile remittent fever is rightly mentioned as synonymous with enteric fever, and among most medical men I presume its close relationship to this fever is now settled. Writers in France, Germany, and Italy acknowledge the same classification. They speak of infantile remittent fever in children as being the same as typhoid fever in the adult, but imamuch as they give it this name they certainly recognize some distinctive feature. We hear members of our profession, especially country practitioners, speaking of remittent fever in children as a distinct disease, and I have found the projudice so great, and the helief so strong, that it has not been possible to convince them of the identity of the two affections. My main object will be to show

^{1 15}th Febris Ephemena.

that this remittent fever, in its severe forms, is intimately connected with the course and complications of typhoid faver.

Typhsid fewer frequently sets in insidiously, initiated by chilliness or slight rigors, frequent and soft pulse; then ensue febrile symptoms and thirst, with diarrhoa and abdominal tendersoo; to this succeed tympanites and gargling in the right iliac fosm. The skin becomes hot, and there is occasional aweating. From the seventh to the fourteenth day an eruption of rose-colored spots appears over the alsomen, there is headache and prostrution, followed by stuporand delirium. After death there is discovered disease of the agminate and solitary glands of the lleum, and enlargement of the mesenteric glands. When death takes place early, the morbal changes are shiefly found in the small intestines, spleen, mesonterio glands, and broughial murous acombrane. The heart may contain congula, and its muscular substance be soft and pale, with or without incipient molecular decay." The spleen is generally enlarged in the first or second week, but returns to its normal size by the third or fourth week.

Whether we call this disease in children typhcod, or remittent fewer, it comes on very gradually in some cases, and note in with severity in others. It follows a course in children similar to that in adults. In the mild form the child is off his appetite and out of sorts for some days; he complains of thirst, is fretful and irritable, and ceases to be cheerful or to take pleasure in his usual anusements; his nights are disturbed and unrefreshing; the howels are confined, and the motions dark and unhealthy, so as to need aperient medicine, or they may be loose and offensive from the onset. Then succeeds heat of surface, followed by persperation and a lowering of temperature. During the first week the abdomen may be natural in shape, and free from tenderness; but there soon follows some amount of tympanites, and pain over one or both iline regions, when pressure is applied with the hand. the evening there is a febrile exacerbation, with accelorated pulse and breathing, the lips become dry, and the tongue is coated on the dorson with a whitish-yellow for. There may be two exacerlations in the twenty-four boars, but commonly there is only one-It is from the recurrence of these exacerbations that the term "remittent" is derived. During the night the child becomes

^{*} Vogel on Diseases of Children, p. 177-

more restless and disturbed; he is wandering and talkative, and the cerebral functions may be sufficiently disturbed to produce delirium; in the morning he looks pule and exhausted, but improves during the day till evening returns, when he is again feverish and drowsy, and this may happen for several successive nights. Sometimes there is a morning exacerbation (about 10 or 11 a.m.), and this has scarcely subsided before the evening paroxyam sets in. He now loses flesh rapidly, and is dull and indifferent to all that goes on around him. During the second week, but saidom before the tenth day, fever-spots make their appearance on the alsomen, though they are frequently altogether absent or few in number, The eruption is of a light-rose color, scarcely clavated above the surface, disappearing on pressure and quickly reappearing when the pressure is removed. All the symptoms increase in severity, and the pulse may reach 140 to 160; the tongue is more beavily furred, or brownish in the centre, red at the tip and edges and contracted; the urise is seasty and high-colored, but sometimes it is clear throughout the fever, and alkaline without the slightest turbility; diarrhum is continuous, and the motions are of a yellowother color, and of a thin pea-soup consistence. In exceptionally severe cases blood and mucus may be present, and when so they indicate more than usual ulceration. About the beginning of the third week, in favorable cases, the symptoms begin to decline and a general amelioration takes place; the howels act more regularly and become more natural, thirst diminishes, and the pulse loses its frequency, the tongue is more moist and clean, and the evening paroxysta diminishes. The child resumes a more cheerful and healthy appearance, but he is left weak and emscinted. When the disease sets in with great severity from the onest, it is accompunied by headache and vomiting, the child rolls his head to and fro on the pillow, and is only half omscious when roused to master a question, or awakened out of sleep. Many of the symptoms are similar to those just described, except that they are proportionately more severe, especially the evening exacerbations of the fever-There is difficulty in forming a diagnosis at the beginning of the illness, as the comiting and cerebral symptoms may lead to the inference that the brain is the organ primarily at fault. The drowsiness is sometimes extreme, and when there is the additional symptom of constipation we may be reasonably mistaken in fixing the true seat of mischief. But soon the vomiting ceases, and by the second or third day the peculiar heavy aspect of forer is recognixed, and the child sinks into a state of stuper or indifference, The skin becomes hot and dry, and the temperature runs up to 103" or even to 105". When it reaches the latter height at an early stage of the illness we may generally rest satisfied that the symptoms are not attributable to meningitis. Fever-spets may now he looked for, but their presence does not seem to bear any relation to the mildness or saverity of the fever, and they are sometimes absent altegether. The pulse is always frequent, and if it continges so is to be regarded as an important symptom. In some children, whose nervous irritability is more marked, it will exceed 140, and remain so as long as the fever and temperature continue high. It may run up to 180 and be too rapid to be counted. "An intermittent palse seldom occurs in children, and I do not rememlee to have ever met with a dicretic pulse in children under ten years of age." This remark requires some qualification. An irregularly intermittent pulse is common in the neurosal affections of children when there is no valvular disease of the heart.

About this time (second week) there is often backing cough and harried respiration. There is constantly to be recognized some rhoncless or coarse arenitation over the posterior surface of the lungs, even if assentiation reveals nothing in front. If the disease has lasted long we shall almost invariably detect these signs, or even crepitant rhonehus with a low degree of pneumonia. If the abdomen has been hitherto soft and free from tenderness, a seesa of discomfort and pain is complained of at this stage, and there is tympunites with gurgling, and the bowels act five or six times in the twenty-four hours; the tongue is more thickly coated, and there is a red streak in the centre, and in the course of the next few days it is glazed, smooth, and red, whilst the gums are dry. During the second week the stupor becomes more profound, or active delirium appears, and the child is nony at night and attempts to get out of bed; he is unconscious of all that goes on around him, and the evacuations are passed involuntarily. Epistaxis is not uncommon. In a fow cases the Madder becomes distended and the urine dribbles away. On examination it may be found albuminous. There may be even convulsions and noisy delirines, lest the insensibility is not so profound as that generally met with in brain affections, and the morbid stuper of fever is characteristic.

⁺ Vogel, On Dissum of Children, 1874, p. 180.

In force we do not as a rule witness the strabismus and irregularity of the pupils, nor the screwing up of the syrible as in cerebral disease. The child may be noticed to pick his lips and nose, and make them bleed, and there may be subsultus. By this time there is great enaciation, and the child is so reduced that it seems beyond the hope of recovery." By the seventerath day, or the close of the third week, some signs of amendment in returning intelligence are observed, and the pulse becomes less frequent, whilst the tongue begins to be moist, and the sordes disappear. H no improvement sets in the vital powers become more and more depressed, the typhoid condition increases, and the child sinks from exhaustion. This is most likely to happen about the fourteeath or fifteenth day, but it may be protructed to the fourth or fifth work, or, indeed, indefinitely prolonged, according to the complications that are present in each particular case. When death takes place during the first week of the fever it is generally due to coreheal disturbance or some other serious complication, as epistax's or intestinal humorrhage. The latter condition is rare in children.

Or the sequelse of typhoid fever in children we may mention diarrhoen, inflammation of the parotial gland, and tubercalesis. Dr. Clifford Albutt has pointed out that the mesenteric glands are often so injured by typhoid fever that nutrition is very much impaired; and it is under these circumstances that tuberculosis is apt to show itself, whilst the period of convalencence renders the constitution liable to measles, scarlatina, and whooping-cough. The mortality is only 5 to 10 per cent.†

In proportion to the severity of the fever convalescence is rapid or dow. In severe typhoid there is great emaciation and nuscular prostration, lasting many weeks, and the child is greatly reduced in firsh and strongth, but bedsores are seldom seen.

Meigs and Pepper say that typhoid fever may attack children

[&]quot;"Whether the massalar mating in fever is the came of an incremed temperature, or the incremed temperature melts show the massalar structures, may not be positively affirmed, but there exists an about an to the field. After a severe pyretic affection, the massles of the links are often stated to an extent quite mappining when compared to the adipose layers. The lax and shrunters hand betchess the diministrative in the halfs of the intercess and other mustles. In hertic fever the massless occur assertions to have almost entirely disappeared at feath, the patient being, as it is added, 'only skin and bose'"—Dr. Milner Fothergill, "On the Typhoid Cambridge," Edinburgh Melical Lawrence, September, 1673.

[†] Meige and Popper, Discous of Children, 1874, p 822.

under two years of age, or as early so the eighteenth or twentieth month, but it must be acknowledged that the disease is rare under five years of age. A case is recorded by Dr. Dunbar Walker, seen in consultation with Dr. West, of "enteric fever in a child fifteen mouths obt," and Dr. Wiltshire also mentions having seen, with Dr. Walters, of Reigate, "a well-marked example in an infant aged six months."

The morbid appearances when the disease ends fatally are chiefly seen at the lower end of the ileum, the most extensive mischief being found near the ileo-creal valve, where there is shown a tendency to destruction of the mucous numbrane, and algoration or even slonghing, or perforation of the peritoneal coat. The glands of Peyer's patches take on the appearance of vesicles or pustules, and subsequently they burst and produce an above, with oval or irregular outline, having thin and undermined edges. The ileum is the chosen seat of these alcors, but they may be seen scattered through all parts of the intestine, large as well as small. It is common to meet with enlargement and softening of the mesenteric glands, and in severe and rare instances they may take on supporation.

Tresherst.-During the gradual approach of the disease, when there is thirst and loss of appetite, the child must not be tempted to take food which it cannot digest. Thirst should be relieved by small draughts of cold water, or toust and water, about a tablespoonful at a tirse, and a simple saline mixture of citrate of potash, so a mixture of nitrate of potash with a few grains of sulphate of magnesia, if the bowels are confined (Form, 8). For the first few days scarcely anything but cold water is required. If the secretions are dark and offensive, an alterative powder of bydrargyrum cum creta with a few grains of rhutarb will be necessary, se the syrup of scaon and rhubarb, or even castor oil, should there be discomfort or pain in the abdomen. When there is tenderness of the abdomen, a warm poultice is comforting; and if there is pain Dr. West recommends a few lesches, which I have never found necessary, and I should try other means before resorting to them. The excitement and postlossness at night may be greatly relieved to the advantage of the patient by brounde of potassium alone, or in combination with hydrate of chical. They have peoped of such value in my hands in all cases of wakefulness from

^{*} Brit. Mad. Journal, vol. 1, 1879, p. 347.

¹ Bids, out it 1879, p. 427.

nersous exhaustion that I recognize them as valuable culmatives in fever. Dr. West speaks highly of a combination of tarter emetic and opium. "A drawght containing five minims of hadanum, and a quarter or a third of a grain of tartar emetic, will be a suitable anolyne for a shibl of five years old, and may be repeated night after night with almost magical effect."+ One dron of husbanum, or something less, for each year of the child's age, in restlessness and excitement, will often induce refreshing sleep; and it may be repeated, should circumstances appear to demand it, without giving rise to any bad effects. If there he much heat of sculp and the vessels are full about the temples, and the conjunctive injected; if the delirium is wild and the excitement force, then we ought certainly to share the head, and apply four ce six leaches. These symptoms often sucremb to the local abstraction of blood, and life has thus in many cases been saved. The load symptoms that occasionally supervene in an advanced stage of the disease are very oninous, and require counter-teritation; they are often attended with squinting, and there is some amount of obsture meningitis with effusion, which may ultimately terminate in neuto hydrocophulus.

The temperature of the room should not exceed 65°, and all unnecessary articles of furniture and luxury should be removed; the clothing should be light, the head shaved or the hair out short,

and the head elevated on the pillow.

During the second week, when the vital powers require support, milk, less feet, and chicken broth will be needed; and, if there is diarrhen, milk, arrowroot, and rice-water, flavored with cinemosu, must be substituted for animal broths. Milk is up to be overrated in fever, for where the bowels are losse and irritable, and the stemach weak, as we expect to find it in the first week or two of the fever, the milk is too heavy to be digested, and the curd, acting as an irritant when the finid pertion is absorbed, provokes diarrhem, and even keeps it up it present. It should therefore be diluted with selecter water, or lime-water, and in many cases it may be replaced by beef ten, or, what is better, barbay-water, beef ten toing upt to induce and keep up purging. When diarrhem is trouble-some, a grain or two of Dover's powder at bedtime, or a starch enems with a few drops of opium, or bismuth will check the irritation. A grain of acetate of lead with acetic acid every

^{*} West on Discusses of Children, 1859, p. 292.

three or four hours is sometimes of service (Form, 29). A mixture containing rhatany root* is an excellent remedy after each evacuation, and the child may be allowed a little port wine in arrowroot.

Stimulants are not often required under ten years of age if the child can digest sufficient nourishment, but cases occasionally occur where life has been saved by a free exhibition of them. A temporaful of brandy every three or four hours in water or thin arrowment will restore the tone of the nervous system, and support the faltering circulation. Alsohol proves serviceable by dilating the outsucous capillaries, and excurraging perspiration.

In the shape of medicine, a few drops of dilute hydrochloric acid with spirit of chloroform, as in the case of adults, will be usefult if there is no abdominal pain or discomfort; and in low febrile conditions, where there is no diarrhora, quinter with phos-

phoric acid is an excellent measure.

Disposais.—The cerebral complications of typhoid fever in children are most important. Like the bowels and the lungs, the brain is liable to be attacked in the source of typhoid fever, and young patients more than those of mature years, are very prope to be carried off by cerebral complications. The febrile process once established creates disturbance and excitement in the nortons

A dissertiques ful there at few times a day. For children from tree to eight years of upo

I See the abstract of a proper on this artifiest read before the Harveinn Scalety by the author. East Med. Jour., Feb. 18th, 1875, p. 122.

system at a time when its active growth and rapid development are ill calculated to bear this extra strain. If simple inflammation of the brain comes on now and then in healthy children, I think it may occur during the progress of typhoid fever in rare and exceptional cases. The blood is changed, the nervous system is excited or depressed at one stage or another, and the functions of assimilation are persected or destroyed, and effete matters from the decomposed theorem are not properly eliminated from the system. Setting aside the injurious effect which the circulation of possened blood at an elevated temperature must have on the norvous centres, there seems no satisfactory reason why the cereteal changes should be restricted to congestion of the vessels, or simple vascularity of the membranes.

Now, it should be fully understood, and experience confirms the truth of the statement, that vascularity of the cerebral mensbranes is by no means infrequent in persons dying from typhoid, where the brain has escaped altogether during the progress of the disease. If the lungs are involved, as they frequently are in typhoid, and there is any amount of pacumonia, or interference with the pulmonary circulation; if the heart grows feeles, from increasing exhaustion of the patient, and its earlities become in any way opprosed, then congestion of the brain or its membrines will be frequently found after death; the cause has been mechanical, and we may term the condition one of "passive congestion." No relation can be established between the cerebral symptoms and the amount of vascularity which the membranes of the brain reveal. If we judge from the character of the delirium, or the convulsions, and the general insussibility of the patient, that these symptoms indicate excessive congestion or inflammators action, we shall be decerred, and errors of diagnosis will certainly lead us into errors of practice.

The diagnostic symptoms of meningitis and typheod force are plainly drawn in our textbooks; but those who have seen much of the cerebral and abdominal diseases of young children must admit the frequent difficulties that beset their path. The worst cases of all for diagnosis are those in which a strumous child is seized with tubercular disease in the abdomen with diagrhen and other intestinal symptoms; there is nothing to call attention to the brain till come or convulsion sets in. Still, the approach of meningitis is slower and more insidious; it is less severe than typhoid fever, and at an early stage very rarely presents the high temperature of the latter affection, which is a diagnostic sign of great value.

We cannot, therefore, invariably separate typhoid fever in young children, characterized by a distinctly remittent type, from cerebral meningitis, especially when the child is under five years of age. The symptoms of one disease or the other must predominate before we can decide with which we are dealing. Usually the bowels are constituted in the cerebral disorder, and comiting comes on without cause, whether the stomach contains food or not; the belly is normal or retracted, the pulse less frequent, and liable to irregularity in force and frequency. Above all, the temperature in meningitia is generally elevated towards the decline of the complaint, and only runs high at an early period in exceptional cases. The ophthalmoscope is another aid to diagnosis in obscure cases.

If the symptoms are mixed together in various degrees, and there is irritation of the digestive organs, and cerebral congestion or inflammation, then, if with severe diarrhox there are thin, othrey, and slimy stools, heat of skin, loss of appetite, thirst, and flushed occustenance, we say this is a case of fever; but if there supervens in a few days uneasy gentures, strabismus, loss of consciousness, picking of the lips and nose, retching or vomiting, then we infer that the brain has been attacked in course of the fever, and the symptoms are the result of exhaustion or overexcitement.

Our disgressis must mainly rest on the order in which these symptoms have occurred. We must not dwell too much on the fever process, and set down the comiting and carebral symptoms to gastric disturbance, whilst the brain has been slowly and imperceptibly going wrong, and is, perhaps, the chief source of trouble.

If the physician is called to see the case early, and an exact account of the mode of invasion has been furnished, his judgment will seldom lead him wrong, if he carefully weighs the evidence on both sides, and notes the absence or prevalence of fever in the same house.

Acute phthisis or tuberculosis may be mistaken for typhoid fever. A quick pulse, hurried respiration, circumscribed flushing

^{*} See Chap. XLII, "Discuss of the Besin-Simple Mesingitis and Tabercolar Mesingitis."

of the cheeks, emaciation, delirium, ancous riles in the chest, and high temperature are common to both affections."

In some adults suffering from typhoid fever we witness the evening flush on the cheek with great regularity and persistence: In other cases, with all the symptoms procisely similar, the face is pullid, and without the faintish boush. This points to a recurrence of the febrile condition with greater force, and often indicates, as the disease advances, serious local changes, either in the intestines, thorax, or brain. So for it is a symptom of grave import when it recurs at a late period of the fever. The periodical flushing is not peculiar to fever as fever. It belongs to the nervous system, and may ensor from many causes. The nervous system is highly imp pressible in children, and their diseases have a great tendency to remission. Witness the flushing of the face and heat of head in some of the cerebral affections of young subjects, roming and going like an attack of ague. Or, again, in dentition, nothing is more common than for the child to wake up restless, with hot head and finshed cheeks. Common gastric disturbance will cause the same symptoms, which vanish with an active purge. Fever affects the nervous system through the poisoned state of the blood, and the depression, the reaction, and the subsidence all depend upon it.

We know that this is the true explanation of the dangerous congestions and inflammation of the liver, lungs, or brain, that are liable to occur in the progress of fever, adding to our difficulties, and taking as out of the prescribed course to meet such serious complications by local depletion, diarctics, stimulants, and so forth.

May we not fairly come to the conclusion that there are degrees, may, even varieties of fever originating from a common cause, and that, whilst it is the exception to meet with a case where there is any difficulty in recognizing the variety before us, we sometimes see cases in which the symptoms are not sufficiently defined to enable us to say what form of fever we have to deal with. Thus, the remittent character of the disease is very well marked in some cases, but to this are added symptoms which some authors have enumerated as belonging to a distinct affection they call gastrio fever, and subsequently symptoms which we regard as belonging to typhoid fever. It appears certain that infantile remittent fever,

^{*} See Chaps, XXXIX, XI., "On Telescolosis," and "On Philinic Palmondia."

well developed, embraces both these types, or rather that identical

symptoms frequently superveue.

There is, however, a coprice in fever which should put us on our guard. The fever-poison, assailing the system for weeks, works such changes in the blood and tissues of the body, that we can never be certain we have landed a case of fever in safety, so long as there is much departure from the standard of general health. Some of the worst cases of equataxis, hierarthria, and bleeding from the howels have occurred when patients have become convalescent from foror, with clean tongue, regular pulse, and good digostion. If we have reason to think that the tone and quality of the blood have suffered much, either from the fever itself or the remedies employed to reduce it, we should as early as prosible begin such treatment as shall gradually replace the solid constituents that have been destroyed. The hemorrhages are not altogether confirmatory of the typhoid character of the disease. Any causes that tend to bring about an impoverished condition of the blood may produce the complication. In sourcy and purpura, and fevers of a low type (in all of which serious bestorrlinge may occur), the changes in the chemical composition of the blood are nearly identical. Intestinal homorrhage occurs in typhoid fever without alcoration; it is met with in cases described by some writers under the vague head of gastric fever. Sometimes, though rarely, a patient successes to homorrhage in typhus also, and it would seem that the fever-poison-whether typhus or typhud, but more especially the latter, and in the more severe remittent forms which merge into the continued type-leads to the same issue,

In one case you will find rose-colored macule on the chest and abdonces, and the tengus red and papille elongated. There is no tenderness of the belly and no diarrheas. In another case the fever is of a very low type, partly from the severity of the poison, and partly from the age and constitution of the patient. The teeth are dry, the tongue is covered with sordes, but there is no diarrheas. On inspection after death alteration is found in the lower part of the blum. We meet with another case in which there is a plentiful eraption of rose-colored spots, but there is no diarrheas; on the contrary, there is constipation, and the bowels are difficult to move. In another case there are fever-spots and severe headache. In another, delirium at night, severe bowel irritation, and rose-colored spots. These cases, and they are not

infrequent, tend to show that the symptoms are not always alike. We cannot say that a case of fover is not typhoid because there exists no diarrhous, and we cannot predict that there exists no alceration because there is constipation. We are accustomed to think that if the bowels are quiet in fever the patient has a good chance of doing well, that the intestinal canal is at all events free from any lesion; but what I think is a surer sign of the mucous membrane being healthy is a normal state of the evacuations, without the offensive odor that is present whenever there is ulcoration. However well cases may be progressing the general health is liable to break down unexpectedly by further contamination of the blood, and the entry into the veins of infectious particles from the ulcerated glands in the intestines. Mere quietade of the bowels is not, as I have just said, any proof that the glands have coraped. Perfect uniformity in the order of symptoms does not occur; discused action is not uniform. It would be neither a safe nor a scientific hypothesis to lay down the rule that all diseases passess a uniform phalanx of symptoms. This is modified and influenced by a variety of circumstances. There is a simple form of fever, and a severe form of fever. Both, so far as our present. knowledge goes, are intimately allied, but one is transient and slight, and the other is severe and dangerous.

To go a step further in the same direction, it would appear that the cases described under the head of gastric fever and typhoid fever are one and the same in their nature, progress, and termination. The stomach may be more involved at one time than at another, as evidenced by the prominent papills of the tongue, and the gastric disturbance and vomiting, but it is the same fever not-

withstanding.

Let it also be borne in mind that constitutional power varies as much as it influences the course of a disease. Vitality is stronger and resistance is greater in some persons than in others. The degree of local change discovered after death is often slighter than is proved to have been present in cases that have recovered. Because some diseases and fatally, we are not necessarily to find tangible evidence of the cause of death on dissection. To some constitutional idiosyncrasy—apart from organic change or the effect of specific poison on the blood and nervous system—we must often ascribe the tendency to sink; so we must also regard as a

mystery that tenseity of life which remains, when all hope of saving it has apparently passed away.

CHAPTER IX.

SPECIAL ERUPTIVE PRVIDE.

Their eliteifestion and proved apoptose—Persions—Various—Character of the craytion
—Diagramic from small que—Treatment.

Tun special cruptive fevers of childhood are vaccinia, or nonpox; varicella, or chicken-pox; variola, or small-pox; rubecia, or massles; scarlation, or scarlet fever. They are all due to the reception of a poison into the system, which, after a variable peried, sets up tolerably uniform constitutional symptoms. There are shivering and rigors, or even convulsions, cold along the spine. los of appetite, headache, languor, and disturbed sleep; then reaction comes on, followed by fever, heat of skin, and the specific eruption. These are the chief symptoms which mark the ordet of the exanthemata. They often prevail as epidemies, and these present very opposite characters in the degree of vascular action and the power of resistance. Though some epidemies are mild, they are as a cale more severe than those of sporadic occurrence, and the severity of the attacks and their complications depend on age and constitution; upon hygienic conditions, and the season of the year. If the health is lowered by previous illness they attain greater force, and the mode of early treatment may determine the result. They pursue a determined course, and active interference is sometimes more injurious than when the unaided powers of nature are left alone, for in this way it is possible to invite various. affections more dangerous than the original unalady. The exanthemata generally attack persons only once in life, and that at an early period. Scarlet forer is the most likely of these diseases to happen a second time, and it is the occasional accompanioned of mearles. Small-pox and measles may also be united in the same individual; and a serore attack of whooping-rough may set in before the latter has departed.

Vaccinia, Cor-pax, or Vaccination.—The virus of cor-pox when introduced into the system produces a specific disease, only modi-

fied by its passage through the cow, or one of the lower animals. Vaccination so induced is protective against various or small-pex. Cow-pex is a vesicular discuse, occurring chiefly on the tests and adders of cows, it is natural to them, and as a discuss of spentaneous origin, occurs almost exclusively to the milch cow, and follows a uniform and definite course. About the fourth day of invasion a few red and tender pustules appear on the tests and adder, which change into vesicles, and pass through the same stages as in man. From the friction used in milking, the vesicles burst, and the lymph which exudes sets up similar seres on the milker's hands, and in this way the disease is conveyed to other animals in the dalar who were previously well and healthy.

After successful vaccination there is nothing certain to be placeved till the third day, when a small red nodule is noticed; on the fifth day an oval or circular vesicie is seen, depressed in the centre, and containing a little lymph. There may be as many spots as penetures a day or two before, but in many cases we cannot say they are due to the virus. On the eighth day the vesicle is increased and threatens to burst, the centre is depressed, and there is a large quantity of transparent fluid. The vesicle is at its highest state of perfection; the skin for some distance around it is inflamed of a rosy line, and the subjacent areolar tissue is hard, tender, and painful. The child is frotful and feverish, and his nights rostless and disturbed. On the tenth or the eleventh day the arcola has extended, and the greater part of the arm may be erythematous. If the vesiele has not been opened it now bursts, and the centre dries into a hard dark scab, and falls off about the twenty-first day, leaving a deep circular depression or cicatrix, with several pits or dots, having a whitish or more pearly look than the rest of the arm. In children who are young and of full limbit an eruption of roscols sometimes takes place on the hody and extreodities, having a papular or vesionlar appearance; it occurs about the ninth or tenth day, and lasts about a week, Vaccination does not follow the same course in all cases, the reside being developed surfer in sesse cases than in others, and instances of retarded cow-pox are assuctimes met with, particularly when dry lymph is employed. When the health is good, children should be vaccinated early, but when they are delicate it should be postpored till they are stronger. "It is enough to state that one fourth of the deaths of small pex in England occurs under the age of one year. Of 20,500 deaths from small-pox which occurred in England in the six years 1856-61, 1800 were in children under one year of ago."*

There is no exact rule to go by as to the time of taking the lymph, as the sesiels varies in its progress to perfection, but it should not be taken later than the eighth day; sometimes it is rips on the fifth or sixth day, and this happens when the arm has become inflamed from the moment of inserting the vaccine.

In vaccinating children some promotions are necessary to be observed. No child who is cut of health, or has recently had sear-latina or measles, or has a chronic skin craption, should be vaccinated. If heils or a pastular eruption follow vaccination they will demand alterative medicine, somes, and good air. These sequely are occasionally intractable, and the alteration on the arm may prove most rebellious to treatment. I have often witnessed the inflammation so great as to require the constant application of load lotion under obtails, or warm fomentations. Wasting of the deltoid, and paralysis of the arm, followed vaccination is a case I saw in 1873. Slonghing and protracted alteration of the shoulder council in the case of a child, four months odd, brought to use in June, 1880. "A case of fittal pyramia after vaccination "is recorded."

I am not an advocate for vaccinating children before the third month, but it is done by some medical men as early as the sixth week.

I prefer vaccination from arm to arm, but where this cannot be done the vesicle should be passetured with a larget, and the lymph collected in an open capillary tube, drawn up by capillary attraction. One end of the tube must be placed within the vesicle, taking care to avoid contact with the blood or pus. When it is full, the ends of the tube are to be closed by holding them in the flame of a spirit-lamp or camille.

In deciding upon the spot for vaccination, the arm just below the shoulder is usually selected, and there is no better, for the part is hidden by the dress of women whether high or low dresses are fashiounble. If there should be a growing news, or other ugly mark on the skin, it may be selected as a fitting spot for the operation, and in many cases it lessens the disfigurement, or destroys it altogether.

Varicella or Chicken-pox.-This disease has also received the

^{*} Vaccination, by Dr. Seates, Beynold's System of Medicine, vol. 1, p. 485.

⁺ See The Lancet, 1865, vol. 7, p. 283.

100

name of awine-pox or hastard-pox. It is both contagious and infections, and the couplion consists of small vesteles about the size of a bemp-seed, which never become postular. It was formerly confounded with small-pox, just as small-pox and measles were mixed up together and not recognized as distinct discuses. It is a discuss of childhood and has never been known to occur a second time. The period of insulation lasts from ten to twelve days according to Dr. Murchison and Dr. Squire. Some authorities make it longer." There is slight febrile disturbance, and the disease ands without any ill consequences, in the course of four or five days. The shill is peorly and off his appetite; there is lassitude and flying pains about the limbs, and the steep is disturbed. Small red pimples appear, which change into vesicles containing a thin transparent fluid, or slightly turbid serum. On the third day they mature and burst, and dry up on the fifth without leaving any mark as in various, or having an inflammatory arcola. The eruption comes out irregularly, and new vesieles may be seen just naking their appearance as the old crop are fading away. It is first observed on the budy and back, then extends to the face and scalp, and lastly. is seen scattered over the extremities. When the vesicles are pricked they collapse, and there is no swelling or distinct elevation of the skin. Children of all ages are liable to the complaint, but it is not so common after the seventh year. It cannot be communicated by inoculation; it is no protection against small pox, and vaccination has no power to prevent the disease.

The diagnosis from modified small-pox rests on the fact that the eruption of varicella is most marked on the back, the face often entirely escaping, and that owing to the eruption coming out in an irregular manner, all stages may be met with at the same place on the same day, whereas in small-pox the rash is either all papelar,

vesicular, or pustular.

The treatment required is confinement to bed, a light fluid dist, and a saline and antimeoial aperient. If any of the vesicles are ambilicated, and likely to have a sear on the face, they may be touched with collection. For any subsequent weakness that remains during convalence, a little quinine or the syrup of the include of iron will be found necessary.

See Clin. Trum, 1878, p. 240, Observations on the Period of Invalation of Scattel Ferry, and of some other Donnes, by Charles Marchines, M.D.

Mesoles is a more prevalent, but a less dangerous disease than scarlet fever, and the greatest proportion of children that fall vistims to it are under the age of five years. In scarlet fever the same rule as to age applies, though not to the same extent. Although measles is essentially a disease of early life, it may occur almost at any age, and few persons at one time or another escape it, whilst scarlet fever frequently squres people altogether.

The period of incubation is such longer than in scarlatina, and extends from ten to fourteen days, during which time the patient is apparently quite well. The eruption generally appears on the fourth day of the fever. In my own family, three children, who were laid up with it at the same time, exhibited a short febrile stage, the eruption appearing on the second and third days of the fever, and cases are unquestionably to be met with where the externial symptoms and the eruption are coincident.†

[&]quot;Mendes and scattlet force were long regarded as varieties of small-pex. Hersian was first distinguished from cariola by Alm Dodnata, and other Arabian physicians in the twelfth content; but mendes and semict fover continued to be looked upon as one disease, which was designated "medicit". An Indian physician, Philip log-main, of Palermo, in the modific of the sixteenth century, first described searles fover, which is called "constita" as distinct from morbidi or mendes, "-d'hard Louise or Medicing by Dr. Minchison. A Case of Extheir, or German Mendes Laures, October 20th, 1856, page 565.

Figure degree of confusion and even error are upt to move in calculating the discution of the invaluation period, some authorities recovering from the time the poison is reveiged into the system, and the first appearance of symptoms, while others calculate from the same period, till the comption shows itself. If the former method of calculation is adopted it will reduce the involution period to ten or elepen days. See Clin.

Three varieties of muscles are described:

- 1. Mathilli milliores.
- 2. Markilli graviores.
- 2. Marbilli nine antarcha.

1. Morbilli.-The discuss sets in with symptoms recembling the approach of a severe cold, or with a convulsive seizure. These are puller, loss of appetite, and shivering; the child is languid and beavy, and fells where it can; headache, droweinses, and restless steep, with wandering and screaming at night, are noticeable warnings. These samptoms are so severe in some children that it is difficult to prevent them from falling out of bed. About the third, or more frequently the fourth day after those promonitory signs, the cruption appears. At first it is not unlike fleshites, and may he seen on the forehead, face, thorax, and neck; in one case under my care the emption in the first instance seized the left closek and neck, and twelve hours slaped before the couption appeared on any other part of the body; there is scarsely any on the arms and legs at the beginning, but in the course of twenty-four hours it extends to the trunk and extremitles, and may be noticed on the back of the hands, the papules being darker, smaller, and less coherent. The eyes are suffused and watery, and the conjunctive injected in most cases; but this is not necessarily so, and the eyes in the worst forms may have a duli look and be free from irritation; or the lide may stick together, and the eyes remain closed during the activity of the cruptive stage. The mucous membrane of the nose and fauces is congested, and there is frequent sneezing; the certical glands are felt to be cularged. The skin is hot, and the temperature may run up to 101" or 1019, but in ordinary cases it will nursly be found to exceed 1029; the pulse may range from 140 to 100, while the respiration is harried and short. The bowels are generally costive, though there may be diarrhosa, and the urine is turbid and contains urates; the tongue is covered with a thick creamy for, which shows points of redness as it is removed, and the whole may become red and moist by the eighth or teath day from the commencement of the symptoms. Plaryngitis, pain in sualloring, thirst, and loss of voice are frequently present, and the irritation extending into the lungs causes loss of sleep and

Times, 1978, p. 258, Charrentions on the Period of Emphatics of Scatter Force, and of some other Diseases, by Clarker Murchison, M.D.

restlesmess." Remissions and exacerbations are common, as in some other discusses of children. Vomiting is occasionally present at the commencement of the disease, but it is far less frequent than in searlet fever, and is not so generally confined to the early stages. In one case, however, a child fourteen months old vonited thirty times a day, and before the couption appeared I dreaded some cerebral affection. "Vomiting countred during the first stage, sometimes almost as late as the armstive period, in thirteen, and was absent in twenty-three enses, of which I have preserved records + The little patients may bring up bile from the violence of the retching, and epistaxis from the falness of the usual vessels. is not unfrequently met with. There may be no therede complication in the shape of cough or bronchitis for the first two or three days of the cruption, but when it becomes more nurked and developed, and is raised above the skin in blotches, the cough is lareseant and irritating, and both small and large conjutation are heard throughout the chest. I have noticed the upper lobes of both lungs frequently attacked, and where the lower were not the first to show signs of mischief, and that, too, in cases which were not tuberculous. This is owing to the extension of the inflammation down the larynx and traches to the broughl. When the eruption is at its height, and the bowels are free, the pulse usually begins to fall in frequency, and the temperature declines, but the symptoms do not generally decrease on the appearance of the eruption; they often increase, and the breathing becomes accelerated and unharrassed. On the seventh day of the fever the emption begins to fade, and by the tenth day the child may be downetairs and well, having scarcely any cough, or in any way complaining. In some cases there is only occasional loose cough, without any physical signs. The emption, too, is variable. On the morning of the third day of the fever it may be conions on the face, and the popular may be distinct and elevated above the

^{*} A felicine boy, upof six years, came under tay care as March, 1817, and on the forth day of the fover the companions was 104.5°, pulse 174, respiration 28; and on the seventh day, when the emption could scaredly be defined, the temperature peached 195°, pulse 290 marriag, respirations 91; there were extensive rides through the front and back of the thest, set the artise and copiese, clear, such specific gravity 1922, and at no time of the illness disk in three clears they aligh the little boy, a few man health. As an instance of angle recovery and commissioners, this little boy, who was mandenth contribe 28th of March, and in a critical state for a week ofter, was receiving about the sund with surposty any trace of extents on the 11th of April.

a 7 the Discouss of Children by Lowin Smith, M.D. Phillefolding, 1983, p. 2011

surface; by the evening the oraption may run together, and assame a large vermilion patch on the check. The constitutional symptoms run high, with considerable fever, thirst, and wandering; next day the cruption may assume a more purple hue, to be again followed by increasing brightness of color. Sometimes it is confinent, resembling searlet fever, and the spots are dark and purplish from rupture of the capillaries, and remain for a length of time, and do not disappear on pressure. Sometimes the rath begins to fade as early as the fifth or sixth day, and from above downwards in the order in which it has first appeared. During the next two or three days the cuticle desquamates in furfurnerous scales, About this time diarches is not uncommon, and if the weather is cold and great provactions are not observed, capillary broughitis or sormonia may supervene. If on the seventh day of the ferer there is an increase of temperature, and the pulse and respiration are also more frequent, we may reasonably take alarm, because the symptoms have beening aggravated at a time when they ought to he letter. In such cases I have known the gruption copious and dusky, with the features swelled, and the lips dry; in a recent case moder my care there was albumen in the urine from renal congestion, wandering at night, and diffused branchitis.

2. Modelli Generices-Malignant Meades.-The symptoms here are more severe from the first; the eruption comes out irregularly, lasts longer, and has a dark-clanet bus, which has received the name of black measles. It is slightly raised above the skin, and has the appearance of petechies. Some authorities do not consider this a distinct species, holding that the darker ofter of the eraption is due to imperfect decarbonization of the blood from palmonary complication. The disease beginning as morbilli mitieres may pass into this grave variety. The constitutional symptoms are of a typhoid sharacter, the prise is frequent and small, the aspect heavy and bloated; the tonger is dry and glazed in the centre, and sorder collect on the teeth; the motions are dark and putrid, or there is severe diarrhos. The lungs are early involved in capitlary brenchitis or posumonia, and death takes place in many instances by asphyala or come. There is dry and constant cough, and the child is drowsy and indifferent. Rilles are heard over the posterior surface of the lungs, and air enters them imperfectly. I have known them so lond, and the mores so great in the tubes, as to give rise to physical signs bearing a close resemblance to the gurgling of a

cavity, and yet in a week after the whole lung has been resonant, while scarcely a trace of broughial irritation remains. The blood in these cases is durk and fluid, and the fibrin and solid parts are deficient.

S. Morbill size Calarrio.—This is by some regarded as morely a mild form of measles without the occurrence of pulmonary symptoms; just as there are also cases in which the eruption fails to come out, and which, with all the other symptoms marked, must be classed as irregular forms of mousles. The fact is, however, many cases of so-called morbilli sine entarrho are really cases of rithele, or nothing more than varieties of crythenes.

The mortality of measles is estimated at 1.15 per cent, but the fluctuation is considerable from year to year. It is essentially a discuss of early life, for it seldom recurs, and, unlike scarler fover, the deaths appear to be greatest between one and two years of age. After the age of five years the mortality undergoes great slimination. The returns of the Registrar-General give the greatest number of deaths before the completion of the first year; the absolute mortality is greatest among male children, but as more boys are born than girls the proportional death-rate is almost equal in both sexes.

Groses.—The disease is due to a specific poison, and it may be inoculated by the blood of a person suffering from it, or the secretion from the nose and air-passages.* The poison is more powerful in some epidemics than in others, which is perhaps due to atmospheric changes; those in the winter months are proverbally more severe than those in the summer months, from the liability to more pulmonary mischief. The same of death among the poor is in many instances passumonia, brought on by want and expessure, and inattention to temperature. An epidemic does not always seize upon unhealthy localities where dirt and destitution abound, or where the water-supply is deficient, but where unrestrained intercourse is permitted to take place between healthy and discused children.

^{*} Drs. Rubbased and Varier, of Birkenheed, here found that glyceria bounked on by a patient suffering from number diving any of the empire days, exhibited tensorous spherical sparking bodies, like show found in receive, but began, and others elongated, with sharp out only specialing and colories. Such particles were not found in given in breakled on by healthy children, may even by those saffering from surrieries or typics. Trans. Path, Sec., vol. axis, p. 422.

⁴ Outroak of Member, Brit. Mol. Joneses, Dec. 1st, 1867, p. 574.

Of the complications of measles, the chief are bounchitis and provincinia, and these most frequently commence in the first stage of the disease when the emption is at its height; or when the patient has suffered exposure to cold; or in its decline, even when the most assidness precautious have been followed. When it does prise during the first four or five days of the fever, the rash often disappears, and the pulmonary symptoms proceed to a fatal termination. The lung speedily runs into hepatization, and there may he searcely any cough to direct our attention to it. Wherever there is any thoracic reasolatef the class should be examined at each visit, for the slight broughitts which almost invariably accompanies measles may creep down into the air passages, and extend to the smaller bronchial tubes and the vesicular tissue of the lungs. The occasional absence of cough and dyspasca should not misland us, when we remember how much the thoracic organs may be involved with little disturbance of their functions. But broncho-pacemosnia implicating the minute structure of the lungs will soon came acceleration of the pulse, and produce some hvality of the features. When these symptoms are present it would be inexentable to overlook the physical examination of the chest.

Another complication of muscles during its progress is an attack of rolitis, in which the motions contain mucus and blood, accompanied by pain and drawing up of the extremities. The solitary glands are inflamed and transfied, a condition which may run on to superficial or despected alteration, and the child may perish from diarrhest and exhaustion. If it occurs after the cruptive stage in the decline of the complaint, it is more difficult to arrest, and may cause death after some weeks. Thus the same tendency to irritation of the pulmonary mucous membrane is upt to extend itself to the intestinal excel, and if, from constitutional weakness, the child's strength is greatly reduced by a slow and imperfect recovery, then phthis is may supervene after many necks or mouths.

Croup is another disease which occurs as a complication of measles. A case is recorded by Mr. Royes Bell, of a boy, seven years of age, in which there occurred on the second day of oraption a croupy cough. The paroxysms of suffocation became so frequent that truchestomy was performed, but the child died of alcoration of the truchest fifteen days after." From my own observation I should say that inflammatory croup or catarrial largingitis

^{*} Case of Museles complicated with Comp. the Luncon, sed. 1, 1879, p. 200.

was not uncommun. It is characterized by soreness of the larynx, and a lond, shrill, ringing cough. The child may cough up a little thin phlegas, but no false membrane is ever formed as in membraneous laryngitis. The aspect is never so distressed or anxious, nor is the voice so subdued, or the cough so hourse. If diphtheria is spidemic when measles prevails it is a frequent complication, and even without this complication the mucous numbrane of the month and pharpux sometimes takes on an aphthous and alternated condition about the eighth day, when the decline of measles is ordinarily looked for."

" for the 17th of April, 1877, at til overche a.m., I movemin the Cherchard, of Maida Vale, a male child, eighteen more though, who are the second deep of measure, one wind with creding of the coveriest global on both sides so as to different the cause of the Jaw. I me him on the eighth day, where the images more was 102.5°, the pulse 120, respiration transpill, the more measurement of the cherchand lips, the rides of the mages, pharma; and modif, were covered with a policiously different constitute, which was fittely afterest to the mucous nembrane in some places, but easily separated in other. The shift could scalless and spack distinctly, but there was transpict in the largest and little proper in the upper broachial takes at revealed by more times. A space of surface and was used (3 in 50) with the effect of distacting a considerable quantity of master from the mechanic, which gave great safety see the government in the Render Ferrar"). At 3 r.m. he was intelligent and clear the global were less swellow, the throat was lost opposited, and the bounting context, but the temperature was 1814 and the pulse small and coming 189, requirement let; the fore was limited, the longer deprint in his large was disposed to slope, and could equilibre well.

On the 18th, 10 a.m., the temperature was 1915. He had been restless and metally all night; there was truck discharge from the month and soutable.

On the Life, 10 a.m., importante 1022. His poweral appearance was better, and his broads had acted very reachy from the mixture of dalactic of punals, quinks, and fillule hydrochloric and artered as the proveding day. At 1.15 r.m. temperature 1922; and discreted and observent, referred had ten, but took with without much broking. To P.M., improved 1027, pulse alignedly better, discharge from month and monther; the agent had been used twice; glands on right-side of face lost studies.

20th, U.A.M., temperature 1018". He appeared wonderfully better, shilling up in hed well looking beight, but he the evening he was more feverish, and the temperature was 101.2".

\$200, 10 a.m., temperature 1015. Loss absorbed, being Boffers and indifferent; there was great differency in getting him to take nontributest. Broady and palls given a very three house. The weelling and inflammation in the thoughout had increased best the discharge was lim, pulse causing and rather feeble. Dif v.M., temperature 1005, pulse will feeble and quiet; seemed daugish when left alone and reducity irritable when detartiod in here food given him; some streams in smallering, but took with without much possing.

ZM resperators 101.8°. Lacked brighter, and glassed about quickly; had taken a piot of milk during the night, and thirty drops of heavily every three hours; the polar was fashle and he was much lacked for sloop. At mother constitution [3 r.m.] the temperature had smalled 100.0°, pulse 125, fields, requiration quiet, the targets was

In three or four instances in my own experience, congestion of the brain and offusion into the restrictes and base of the brain carried the children off.

Among the significance enterum oris, and a severe and troublesome form of strumous ophthalmin, leading in many cases to ulceration of the corner and permanent damage of the organs of vision. Otorrhora is another common affection, so is suppuration of the cervical glands; obronic diarrhora, phthisis, croup and enlargement of the measureric glands are also among the consequences of the disease. When whosping-cough follows, it has probably been contracted beforehand.

Except in the malignant form, measles may be considered a favorable disease if the febrile symptoms are moderate, and the

partially covered with a second excitation at the sides, incide of checks and lips, and there was a small, irregular, dirry when below the infector incides tooth; the pluryus was not and smollers, and an articupe at experiencing distributed from the air-present a good deal of mean-purches; excretion; the most passages mere also discharging a watery, glulry so-return, but in no way efficueive; the strine was clear and how albumnous. As there had been some purping from the oblemic of possels and quintine mixture, Dr. Cleveland gave live minutes of timeture of the perchloride of iron in a little symp of consecuent curry tear hours; a positive was applied to the threat.

5M, 10 a.M., temperature 101.27. The month was less smiles; he resiliered soil and shock will freely. At 10 p.m. the temperature rose to 103.47, the glassis and

threat more times to allow, and he was reallow and averse for unarjulenced,

20th, 10 A.W., temperature 101.4", palse 126, respirations 40. The longs were clear and resonant throughout, and there was neither difficulty in scalinging are enhancement in respiration; a large white apirthons patch covered the bellow of the hard points and the magne; the neck was much sentien, but an eige of supparation. The tem and obtains of potcols mixture was resulted. If r.M., temperature 102". General appearance shall and habite; would take nothing but milk with a tittle brands in a

Sith, 19 a.m., impression 1988. Throat much loss swyllen, and general appearance beginner; was interested in his playthings, and sulked a little; discharge from rise less, but illing entire was discharged from the month. Had taken a quart of milk and two rups, and occasionally half a temporatal of farmily in twenty-four hours.

27th, 10 a.m., temperature 69.5° Novel discharge had consed; the morth wat much cleaser, and the contribut distributed; correctly glands much method in size, but the phosymposi polynosi contensed. 10 t.m., temperature 761°; pulso good; storps well.

25th, 10 a.m., irrepresent 95.4° Had monkedily improved, and eatup for a short time near the fire; glassic again smaller in size, and no difficulty whatever in realiseing. Has complained for two days of temberanes about the stress of right arm, and to day both arms seen affected with risemunium.

Mrs 2d. Had bull prime in the parts had effected to, but he can along the more, and was removed to his mother's boson, some two miles distant; temperature 90°.

May 13th. No complaint of pain way; the after on the mode of the lower lip hid not he field, but the glands of the seeds were natural, and he was in every respect overall more.

emption, it is to be viewed with apprehension if the skin is hot and day, and the respiration forwied. If the fever increases after the appearance of the rash, and the pulse becomes quick and small, the patient's condition is alarming; and if pacamonia or whoopingcough, or constant diarrhees be present, the danger is proportionately greater.

Treshami,-The temperature of the room should not be less than 70°, and all draughts should be exceptly excluded. In mild cases it is only accessary to confine the patient to bed, and to maintain warmth and a gentle action of the bowels. For the first three or four days the diet should consist of gruel, milk and water, thin beef ten, or chicken broth. Barley-water flavored with lemon, finesed ten, and the inhalation of steam will be grateful to the were and inflamed moscers membrane. If the febrile symptoms are considerable, a dispheretic mixture" with a little autimouis! wine every four hours, or a saline aperient, will be necessary to encourage the action of the skin and bowels. Sometimes a warm bath, if the skin is dry, to promote perspiration, will be found serviceable. When symptoms of exhaustion are threatening, the carbonate of ammonia, with a little spirit of nitrous ether, may be given, and alcoholic atimulants, if they seem to be demanded, such as brandy or shorry beaten up with egg; and mwsbeef juice has proved useful in cases that at one period of the illness appeared hopeless. If the cough is very troublesome, and the patient can obtain no rest at night, a little ipecacuanha wine with morphia, or the compound fineture of camphor may be prescribed when the lungs are not overloaded with mucus (Form, 77). Hydrate of chloral, with ayrup of tolu, or these combined with bromide of

potassium, will allay excitability and promote sleep, whilst a marm bath is enothing and hastens the process of desquamation.

When the pulmonary symptoms are severe, and there is drawn, pere, blood should not be taken from the arm, but engging between the scapole may be reserted to if the pulse is small, firm, and hard, and the rash well out. After this the nir will enter the lungs more freely, and the duskiness of the emption will be exchanged for a more general redness. In the malignant form of the disease, where there is a typhoid condition, the strength must be supported from the first, and eggs, beef too, milk, coffee, ste, must be regularly given. Brandy or wine should be mixed with an egg se milk, and given, act with standing any delirium that may be present. If the breathing is hurried, or there is dulness or crepitation in the lungs, and especially if there is any difficulty in expectoration, carbonate of ammonia, spirit of chloroform, and senega will be necessary (Form. 69, 70). If the eruption is dusky, or disappears too suddenly, and there is any oppression in boutleing, mustard poultiess should be applied to the clast, the Set plunged into warm water, and wine and diffusible stimulants freely given.

When the child begins to recover, and during convalencence, it cannot be too much insisted on that all chance of cold should be carefully avoided, as neglect of this rule may, by weakening the general health, invite some of the troublesome sequele we have alluded to, and among them tuberculosis; for messles seems to have the power of especially rousing into activity the various forms of scrofulous disease. Warm clothing and flannel seem sext the skin are most important, and sea-bathing and cold sponging are very valuable, if used in proportion to the strength and constitution of the child.

When measles has been severe, and has reduced the general strength by rausing some degree of subscute pneumonia, or chronic intestinal disorder, it is sometimes followed by a voracious appetite, and a sensation of hunger approaching to bulimia. This is also noticeable as a sequel to some other diseases of children where digestion is imperfectly performed, and the absorption of the chyle does not ensue owing to disease of the measurerin glands. If, berause of this insatiable appetite, food is injudiciously given, the digestive organs are never rested, but grow weaker and weaker, whilst the body slowly wastes. In these cases the complexion is wan and pole, and nothing does any real good. The tongue is commonly covered with a light fur in the centre, and the papille are prominent, the spithelium peels off in places, and it presents a sere and ragged appearance. These obliders awallow their food as soon as it is in their months, and thus prortax the feeble mutions membrane. The rational trentment consists in restraining the child's consumption of food, and giving at first an exclusively milk diet, and, later on, but ten, eggs, etc. Medicinally, a few grains of chlorate of potash, with dilute hydrochloric acid, will be useful." Quinine, steel wine, and, above all, cod-liver oil will be found of the greatest service during convalorance.

RÖTHELN, OR OREMAN MEASURE (BUDGOLA SOTHA).

Panally a solid affection, a combining releases marrier — Personaling four action crossists in married four four all the combined and the combined form in combined — Original phones shipling solidayed—Symphonic and treatment.

Richler, or German accounts (accounting accounting applied account of the profession), it is reckened as a mild affection, and frequently fails to come under the notice of the great bulk of the profession. It is still, however, of importance, and possesses a few special poculiarities with which we eaght to be acquainted. Formerly some observors regarded the disease as a modification of measles and scarlation. I am disposed to think that doubtful cases of crythema or urticaris are sometimes mistaken for measles or scarlating; for it is certain that in practice we encounter cases of febrile excitement in young children attended with an obscure rash which it is impressible to classify under any recognized exanthem. It is probable

that Vogol," under the title of rothelo, describes the same disease as the one under consideration, though he says the duration of the craption, which is considered the most characteristic symptom, lasts only one, or at most two days, whereas Murchison and Liveleg say that it continues four days. These writers both speak of the occasional presence of catarrh, whilst the German author notifies its uniform absence. But probably different epideules vary a little in their symptoms, as we find is the case with conmon mession.

The discove presents some symptons allied to, but many unlike, the common form of measles. The eruption is said to partake of the character both of measles and scarlation, yet it is now regarded as specific and distinct from both. The swelling of the throat and tonsils, and the white coated tengue, followed by reduces and enlargement of the papille, resembles scarlatina; while the catarrh and congestion of the air passages liken it to measles. But it is less acres than either of these fevers.

In severe cases the complaint is ushered in with shivering and febrile disturbance, businehe, pains in the limbs, sero threat, redness of the pharynx and tensils, and in some instances nansea, and even vomiting. In addition to these symptoms, the respiratory organs are sometimes slightly affected, and there is extarrh, short engls, sneezing, and coryga. There is not this complete set of symptoms in all cases, but some are usually present. The semarks able feature of the affection is, that the premonitory fever, instead of lasting three or four days as in common nearles, solden con-

^{* &}quot;The grandent differs in no respect from that of modelli; small round spall of the rise of featile cores the suries body, combaning, in most manage, a considerable are even of highling. times more than twenty-four hours, when the rash makes its appearance, and hence, if this he true, we have a means of diagnosis which is distinct and valuable.

The eraption first appears on the thorax and arms, but often on the face and neck; it is characterized by small, red, slevated patches, or distinct and minute round papules. They semetimes coalesce and run together, forming large and irregular patches, and when the patches unite, the body becomes universally red, and the eruption resembles that of searlet fever, being brighter than that seen in measles. When the rish disappears the skin may designamate in brauny scales, so we cannot attach much importance to desquamation as a diagnostic feature. "The eruption is copious in a direct ratio to the severity of the general symptoms,"s With the appearance of the ecuption the throat affection is apt to increase, and the swelling in rare instances becomes so great that the patient is unable to swallow. The cervical glands, top, become inflamed and enlarged. + "The protracted duration of the cruption is certainly one of the characteristics of the malady, though no doubt a more or less variable one, and of little or no value as a means of early diagnosis. In the case under my care in the hospital the cruption lasted from five to seven dars, a longer time than is usual either in measles or scarlet fever."! It appears to me that not much reliance can be placed upon the damation of the cruption, or to the extent of the desquaration, as in one case of ordinary menules under my care in April, 1877, the skin was desquamating at the end of a month, the eruption though finded was distinct at the fourteenth day, and after washing, it was quite bright on the extremities, neck, and shoulders.

Another very important feature of rotheln is that it never produces measles or scariatina in others, so that, from this point of view, it is entitled to be regarded as a distinct and independent

disease. It has a tendency to propagate itself, and spidemics of it have been recorded, but it is doubtful whether the disease is so contagious as the other exanthemata. It affords, moreover, no protection against the two diseases to which it hears a close resemblance, for some children who have suffered from it previously, and others subsequently, had both searlation and measles; and those suffering from it have not, in a single instance, communicated either of these batter diseases to others.

The disease, though highly contagious, appears to be more epidemic than massles or scarlatina, and is a milder affection than either. One attack is protective against a recurrence of the disease, but not against a subsequent attack of common measures.

The idea has been started that rotheln is common measirs molified by a previous attack, but the fact that rotheln frequently procoles measirs is conclusive against this view.

Allominums and dropsy are rare complications; those file euros may result from the temporary renal congustion of ordinary measies, but their absence distinguishes them from the sequele of scarlatina.

I would again repeat that the type of the disease varies with the particular epidemic; a fact which is too upt to be lost sight of; and which explains the slight differences in the descriptions of authors.

The treatment consists in confinement to fiel, a felerifuge mixture to encourage dispheresis (Form. 7, 12), and, if entarrhal symptoms arise, demolecut and solutive remedies (Form. 65, 95, 74) as the case may appear to demand them.

Scanner raves, or scarlatine, may be defined as a contagious and infertious fever, attended with a scarlet rash on the body, and with inflammation of the throat and famous. Three varieties are described:

- 1. Scarloting simplex.
- 2. Scarlitina unyisson.
- 3. Sarlatisa noligas.

Scariatina has three well-defined stages: I. The premonitory seincubation stage. 2. The stage of eruption. 3. The stage of decline and desquaration.

L. The incomplion stage lasts from the day of infection till the commencement of the febrile symptoms, and is usually shoet. It may extend from three to five, or even eight days. In some instances the period may continue only a few hours.) There is no

[&]quot;The term 'Scarlation' is said to have been the removaler more for the disease to the electron of the Leyant, and sees that adopted in a modical work by Prosper Machines, smother Indian physicism, who, about the middle of the sixteenth century, also described the disease as distinct from morbilli. Epidemian of searles force were first described in this country by Sydemian in 1670, and about the same first in Scotland by Sir Robert Sibbald, physicism to Charles II, and in the middle of Los country by Pothergiff and Haximan."—Clinical Lectures on Mathebas, by Dr. Marchana, Case of Bathelm or German Mession.—The Lengt, Oct. 20th, 1870, p. 590.

[†] DV 75 cases collected by Dr. Marchison, the Intent period was few than twentyfour fewer in some, and in some did it exceed six days. - Clin Trans., 1876, p. 257.

exact rule to go by as to the duration of this stage; one child will resist infection for a longer period than another, or the infection, will be slower in disturbing the constitution. Some children are more susceptible than others; and the character of the spidemic may differ in severity. A child may be finling out of sorts for days, langual, depressed, and "off his appetite," but the illness excites no approbancion if scarlet fever he not prevalent at the time. When chilliness, thirst, quick pulse, and increased temperature of the skin sucreed, the parents become anxious. Diagnosis is even now impossible, but if there is mausen or vomiting, and the tonells and famous are inflamed during the prevalence of an opidemic, we can scarcely mistake the character of the feyer. As the case progresses the breath Iscomes intensely hot, the skin pungent and liurning; and, towards the evening, or during the night, the cerebral functions may be so disturbed as to lead to convolsions or delirium. At this stage the characteristic emption will appear, and it is soldon delayed beyond twenty-four hours.

2. The craption street is marked by small red points upon the face and neck, which extend to the trunk and limbs, especially the inside of the thighs, and the fexures of the joints. In the course of twelve, or at most twenty four hours, the cruption assumes a general crythenatous appearance, and the little patient Lesomes as red as a "boiled lobster." The rush, however, is often variable in severity, and mixed in its character, so that a young practitioner might be excused for overlooking the nature of the case, when distinct large or small red spots are disseminated over the white normal surface of the body. When the spots are small, srattered, and dusky, there is ground for alarm. When there is a well-developed eruption it relieves the internal organs from excessive oppression by the fever-poison. The eraption is brightest in healthy and strong children, whereas in the feeble it is limited, and the spots approach a claret line. The oraption of scarlatins, as well as the constitutional symptoms, attain their height by the second day; the emption begins to decline on the fourth, or at the latest on the fifth day, when the throat becomes easier, and tranquil eleep returns.

The threat of scarlation is never so painful as it is in severe tomillitis, where the swelled tomils almost occlude the pharynx from tumefaction and threatening supportation. The tongue is

^{*} The diagnosis of the throat effection is considered in Chapter XXX, On Diphtheria.

very characteristic in most cases, but, like the cruption, does not invariably assume the same appearance. When the cruption is brightest and inflammatory fever runs high, the dorson and centre are covered with a white creamy fur, and the elongated popilise project through the deposit, giving the tongue the appearance of a white strawberry. The temperature frequently runs up to 105° or 106°, and some of the worst, and even fatal cases in children, have not exceeded it. It has, however, been known to exceed 112° in fatal cases. The fever and the rush appear to hold a close relation to one another, and they subside simultaneously, leaving the patient weak and languist. In the decline of the discoe, the urine frequently contains albumen, and the child is pute and thin. About the third week after apparent and complete recovery from mild scariet fever, answers and albuminuria may set in.

3. The stage of dispressation.—The skin begins to peel where the cruption first made its appearance, and if it has been copious, the old epidermis may exfoliate in large scales, or come away from the fingers like a glove; the process is a very slow one, and if precantionary steps are not taken may extend over many weeks. The nuccous membrane also participates in this process, by the escape of phlogm from the fances, and spithelium from the renal passages. The motions at this period are also putrid and offensive, and indicate the precound effect of the fever poison on the two chief ex-

eretory chappels.

1. Seveleties Simplex.-The disease begins with the usual symptoms of fever; thirst, quick pulse, hot skin, handache, pain in the back and limbs, restlessuss and distorbed sleep. On the second day of the fever, a bright red scariet efforescence appears, having many red points, which are not elevated above the surface of the body. In some parts these small points run together, and cause the reduces to be general; whereas in other parts they do not coalesce. The graption is first seen on the face, neck, and abdomen, and especially over the thorax and bends of the joints. On exposing the back and loins it may be often seen most distinctly. The esuption disappears on pressure, and returns at once when it is removed. About the fifth day the rash declines, and by the eighth it fades and disappears. The cuticle begins to peel and separate about the fifth day from the parts first affected, and this process may continue for many weeks. The hands and trunk may be seen to throw off small or large scales; and, whilst it lasts, there is great irritation and itching of the skin. At the commencement of the disease, before there is any rash on the body, or the threat is sore, there is pain and difficulty in swallowing. On looking into the throat the tonsils are noticed to be swelled and inflamed, and lymph may be seen adherent to them; there is diffused reduces of the soft palace; the uvula is also red and slongated, and the pharynx inflamed. The tongue is covered with a thick white fur, and the papille may be seen through it. Sometimes in the course of two days the fur disappears, and leaves the tongue of a strawberry hae, or it is red and strawberry looking from the first. The appearance of the rush is not attended by any satisficace of the fever, the skin being hot and huming, and the temperature elevated, with wandering and delirium at night; there is probably no discuss in which the temperature runs so high. Ventiting is a common and early symptom. I have constantly observed it before the rash, and in this way anticipated the disease. The pulse is frequent, full, and compressible, and ranges from 120 to 140 in a misute. The urine is scanty and high-colored, containing senter at an early stage, and commonly albumen later on. During the fever the amount of area and uric acid exercted by the urins is increased, while that of the chlorides is decreased." The righdoes not always appear on the second day; it may be delayed in some cases till the third or fourth day, or commence on the first day of the feror. In the mildest cases there is little else noticeable than a general crythema of the skin; there is no pain in swallowing, nor inflammation of the tomils or pharynx, or, at any rate, the reddening of the throat is so slight that it may well escape attention. The cruption comes out and continues the usual period, followed by desummation,

2. Southing Agginson.—Here the throat is more severely affected, and the submaxillary glands are frequently enlarged and tender, so that the patient has pain on opening his mouth or in swallowing; the tousils are covered with a fibrinous or sloughing exudation; one touril may be more affected than the other, or neither may be implicated in this way. On the first day of the fever, before the rash appears, I have seen the right tonul excavated by a deep, ragged, ashy-looking alove, and the tongue louised with a creamy for at the back. I have also noticed a similar

^{*} Clinical Energy, History of Souriet Ference-Lie, Rightschutz, Aschepini, vol. 8, p. 114.

ulcer on the lifth day of eruption, and general inflummation of the pharynx and uvula, whilst the fur is deaning off the longue. Mucus collects about the fances and throat, oursing troublesome hawking and spitting, as well as heavy breathing, and the inflammation extends to the nose or runs along the Eustachian tube to the car: In one case the whole external err assumed an erysigeiatous reduces, and there was much deafners. The putient recovered without any occurbes, and with unimpaired bearing. As in the former variety, the oruption comes out on the second day of the fever, when the threat usually becomes essier; the emption. may appear first on the arms and chest, for the reason probable, that protected parts are least likely to be chilled. The rest of that throat may now he swelled, and the left toroil may present two or three small ashy sloughs, like the right. The pulse may reach 120 or 140, and the respiration become accelerated. The urine as this stage is turbid, often high-entered, and contains a large quantity of lateritions sediment. In some cases the swelling of the throat increases, and the voice becomes busky and weak, though the pulse may have fallen in frequency. On the third day of the fever the cyclids may be swelled, and the conjunctive so inflamed that the patient cannot open the eyes; it leads sometimes to ophthalmia tarsi, and repeated small abscesses in the lids. By the fifth day the extension of the sloughing may have censed, though fresh portions of graylsh slough may fix on the uvula, and on any sound part of the tonelle. The skin now becomes cooler, and the temperature falls, the profiness of the face subsides, and the songue cleans. The cutaneous irritation at this stage is extreme, and in some rates prevents the patient from obtaining any rest or sleep. Severe febrile symptoms may arise in less than twenty four hours after infection. In 1869 I was remmoned to a young person who the night previous was in good health, and walked and drove out. At my visit, at 9.50 p.m., I found her with high fever, hot and burning skin, great thirst, and loaded tongue; pulse 120, very weak, fremer in the legs, and prostration of strength. Both tousils and uvula were much swollen and inflamed, and on the right tossil was a patch of yellowish-looking lymph. There was pain, and difficulty in deglatition, but no houseness or calargement of the glands in the neck. She had been very sick in the early part of the day, and brought up clear bils. The following day the face was much flushed, and a copocus eruption of scarlet fever came out

on the chest, abdomen, shoulders, and loins; the skin was hot and perspiring; temperature in axilla 104°; in mouth 105°; pulse 129, firmer and fuller. She could speak more distinctly, though the swelling of the throat was greater, and the lymph on the tonsils was increased. She was in all respects note comfortable since the cruption had appeared, and sickness had entirely subsided. For the next two days the patient remained in the same condition, when the throat became entire, and she could speak with case and charmens. From this time recovery was rapid, and the convalencence uninterrupted.

In some cases this variety of scarlet fever is attended with more severe constitutional symptoms than those I have connecuted; sleep is disturised, and exhaustion sets in early; the pulse is frequent and feeble, the secretion of urine nearly suppressed," and effection takes place into one or more of the chief cavities of the

bolt.

Southing Meliper (Cynanche Maligna of Culten).—This is the most alarming variety of all. The disease concentrates its virulence on the throat and tonsils, where dark, offensive exudations form, with deep asky-locking alers and stoughs. The pharynx, availa, and part of the hard points are sometimes seen covered with a gangresions deposit, and a bright-red line of demarcation is visible. Similar alcoration may also be seen on the inside of the checks in severe cases; the nostrils also become inflamed, and furnish a thin, irritating discharge, which inflames and excertates the fig. The salivary glands are also inflamed and swotlen. The fever at an early stage of the discase assumes an adynamic type, and the constitutional depression is severe. There is wandering and drose-

^{*} Long in constitution a latte bay, in 1878, who on the fifth day of the craption passed only two temperature of minus in recent-dur hours, containing a commitmable quantity of bile pigners and a trace of silburiers, or that there was anaple proof of cety defective elimination. The patient was word, realters, and wardered at night; the threat was unversely affected, and there was a difficulty in getting him to take married ment. A positive was applied to the losin, and next day a free correction of arise back place, in which neither hile nor alburier could be delected. Mr. Naugistia, of Bakes Street, informs me that he attended a child, agol see yours, in 1870, who did not past urine to move days, and she was delected the whole time. The approxime case us ten days after the straption had finappeared, and it assumed traceable to using hearthy of indignatible field. There was no consisting. The first urine posed after this long interval was about a compositely, and approached the other of ink. As the quantity harmond the rolar because turned, and the patient experienced as necessary receivers.

siness, or great irritability and restlessness; the pulse is feeble and mold, or irregular; the tongue dry, brown, and chapped, and sordes may be seen on the lips, teeth, and gums. The temperature runs high; in a fatal case under my care it resolved 108°. Sometimes the patient dies before the abortive scuption comes out. There is no uniformity in the time of its appearance or in its charneters; it is often dark and in irregular patches, or it may be pale and beight at first, and then change soon to a claret line, some spots being larger than others, and there are also observed in some cases petechise, which prove that the blood is much changed. The disease in many cases proves fatal on the third or fourth day. How far this variety differs from the others in its real nature is still an undetermined question. Is not the disease the same in all cases,-a distinct favor, brought about by a specific poison, but from constitutional predisposition, locality, physical conditions, or extreme susceptibility of the organism, assuming a mild or a severe form? Epidemics vary in their severity, and produce varieties of type, but a number of collateral circumstances must be ranged side by side, before we can admit aux essential difference in the pature of the disease.

There is a form of latent searlet fever (analoting sine eraptions). which is of so mild a character that the disease is not suspected till the general health shows signs of failure. I have seen childres on various occasions suffering from aniemia and general delibity, with or without albuminuria, who have had some deequamation of the skin without the specific proption. In one case, a little girl, who was said to have escaped the disease when her brother was laid up with it, came under my treatment for symptons of general debility. Her urine was scanty and non-albuminous, and there was not any sign of arasarca, but I could not avoid associating her state with the probability of infection. She may have had some sore throat and feverish disturbance, but they were not noticed by the mother, though lar skin was rather hursh, and the epidermis inclined to peel at the tips of the fingers. Cases of anasarus occasionally come under our notice which have had their origin In the poison of searlet fever without any eruption. The absence of cruption, and the slightness of the illness, have crused the child's state to be overlooked, and the necessary precautions for avoiding cold and exposure have not been taken. These patients are capable of communicating the disease to others,

As regards the pathology of the disease, I may here give the views of Dr. John Harley," who describes scarlation as essentially n disease of the lymphatic system. How far these views may be correct appears to me one of those perplexing questions which further observations only can determine. Dr. Harley gives the post-mories appearances in twenty-eight fatal cases, and the morbid changes described appear in many of them to resemble the first stage of enteric fever. The glands of Peyer (glands)s agminute) were purple, swellen, and vividity injected, and the timeous membrane of the small intestine was of a pale or bright rose color. The solitary glands were also prominent, and of a yellowish order, "so that the lower third of the ileum appears as if aprinkled with grates of sago"-presenting eminences like hempseeds. This appearance, which French writers call "Patrenterie," was observed in most of the cases. The solitary glands or follows of the large intestine were also swellen and purple, and the evenue, where they exist in the greatest number, is sometimes series on gested and inflamed. The speen in some of the cases was greatly enlarged, and as firm as liver, the mesenteric glands were likewise turgid, and unlarged to the size of a pigoon's egg, and the mesentery has been found converted into a thickened loculated mass, resembling a big of large or small mariles. The right excities of the heart were often distended with blood, and contained colorless date of entangled fibrin, adheront to the charde bradings, and cominging through the sericule-ventricular opening. These wormlike clots extended into the pulmonary artery, the superior cava, and larger vessels of the neck, as far as the omnial cavity. Branches may also be sent into the lungs, from which they may be withdrawn eight or nine inches long. The same may be seen in some cases of surgical perexia where a clot is forming in the heart. Oppression and severe pain in the cardiac region, orthopousa, a rapid and feeble pulse with an alteration in the beart's sounds, indicate that a deposit is taking place.

The left side of the heart in the twenty-eight cases alluded to was generally found empty and contracted; there was only one case in which a fibrinous clot was found in each cavity—in this case there was a fibrinous clot on both sides. The tendency, according to Dr. Richardson, is to the formation of clot in the right

[&]quot; Mod-Chie, Trens., vol. by, p. 193. The Primotogy of Scartinian.

eavities, and from what we learn in some other diseases where the temperature is unusually high, it is what we should expect.

The lungs were deeply congested in some of the twenty-eight cases, and points of occlaymosis were som on their ploural surface, and also in the parietal pericardium. Pericarditis and pleuropneumonia are occasionally present. Hiemogrhage from the lowels was the cause of death in one case, and scarrely any part of the mucous membrane was healthy; there was bright-red villons exudation, and the thin vascular mendeaus came away exposing the lound, which was lifetched and spotted with earlymosis. General inflammation of the mesenteric glands and those of the pleara are constantly observed, and profuse diarrhea with light slimy stools. as we observe in typhoid fover, are features of clinical interest, Out of the twenty-right cases, more or less albuminoid or fatty degeneration of the kidneys existed in six. Most of the patients died from the third to the sixth day, but kidney change occurred in no case before the fifteenth day. The bile was found normal only in five cases out of twenty; in the remaining fifteen it was much deranged; the specific gravity was low (1014) in thirteen cases, and the solid matter less than a third of the normal amount; the biliary acids were deficient, but the coloring matter was never absent.

The minute pathological anatomy of scarlatins, according to the most recent researches of Klein, consists mainly of changes in the kidneys, liver, spicen, and lymphatic glands of the throat. In the kidneys there is a preliferation of epithelism cells, and changes in the walls of the bloodressels. Later on, there is a development of round cells which constitutes a true interstitial nephritis, due to an embelic process. In the fiver there is also a growth of round cells and thickening of the walls of the bloodressels, with an infiltration of the interlobular and intrabbular connective tissue. In the cervical glands, there is inflammatory swelling and multiplication of the lymphatic nuclei, and in places, large glant cells containing several nuclei. There is also a hyaline thickening of the arteriolos.⁴

During the last few years many writers have noted the association of searlet fever with enteric fever, or one has so rapidly followed the other, that they have been naturally regarded as holding some relation to one another. The cases recorded by Dr.

Harley show that scarlating coexisted with enteric fever in a few of them, and that rose spots were distinguished on the abdomen and chest, when there was a general souriet rush on the body, Paymies were also seen distinctly on the pullid skin after the scanlet blush had faded away. The account given leaves little room for doubt. Diarrhora is common to both diseases in their decline, and the evacuations are alike in character. The tongue in typhoid fever often presents a red angry appearance with enlarged papelle, as we observe in scarlet fever. We have much evidence to show that mixed cases do exist, and that the two morbid conditions cannot be separated in a few instances where the febrile process is prolonged. The fact of diarrhem being present in the latter stages of the disease is fully explained by the state of the intestinal glands, and we must, I think, agree with Dr. Harley that this morbid change is one of the strongest proofs that a pathological relationship does exist between the two diseases, which notidental interentrence falls to explain.

Whatever the resemblance of the pathological states may be, in some cases, such as Dr. Harley relates, the two diseases in their local and general signs present on the whole a striking contrast. If a shild goes on well for the first week or ten days of scarlet fever he commonly gets over the attack, but in typhoid fever the disease is lingering and slow, and this scenrity cannot in most cases be felt till some weeks have clapsed. There are crises and relapses which expose the child to danger till convulsames is permanently established. The violence of this short fever is not so alarming as in some others, and cannot be speedily out short. It is less alarming in searlet fever than in almost any other complaint. "Delirium," says Dr. Gairdner, "is upt to ambilde of itself, and may be safely neglected; it will disappear as soon as the crisis is fully established." He quotes the opinion of Heberden, who also outertained the view that there "was no disease in which the putient was more apt to be delivious, and with less danger, than in scarlating."1 Such remailies as antimony and opens are out of the question, and shaving the head to meet the delirium would only be necessary in exceptional cases. When defirium arises the little patients should be carefully wanded and tended, but excessive interference is had practice, and does an infinity of harm.

^{*} Clinical Medicine, by Dr. Gaintage, 1962, p. 1931.

Greek.—These are due to the influence of a specific and highly contagious poison. The poison retains its power for a considerable length of time, and the clothes worn by patients suffering from it, as well as carpets, curtains, etc., absorb it. There can be no doubt whatever that undical men sometimes convey it from patient to patient, and so carry it to their own families. Infection is as great at the beginning as during the time of desquamation, but it is worthy of notice, that some persons are more susceptible to infection than others, and that a server disease though apt to produce its like, may also result from a mild one.

Children at the breast are rarely affected by searlet fever, but such cases are recorded; the disease is more preue to occur about the second and third year, though there is very little difference up to five years of age, and after this period the deaths undergo a remarkable diminution, but nothing like that observed in measles. Then with regard to the proportion of deaths in the two sexes: more males are said to die under the age of ten, and after ten more females; but as the population in any given district may vary considerably between the two sexes the distinction is not easily recognizable.

As to the influence of meteorological conditions most writers agree that the disease is most prevalent in the autumn, and least in the spring; next follow the summer months, and lastly the winter.

The average annual mortality in England alone from this terrible scourge is estimated at from 20,000 to 22,000. It is greater in towns and cities than in rural districts, and stands highest on the list of communicable diseases. Then follow whooping-cough, nearlest, and small-pex in the order I have placed them. Although searlet fever rarely happens a second time, numerous well-authenticated cases are placed on record. When it does happen that a child is seized with a recurrence of the disorder, it is exceptional, and so mild in its nature and progress that it never proves fatal.

Concerning the recurrence of searlet fever many examples are to be found. A case occurred in the London Fever Hospital under the care of Dr. Broudbent, where the patient had a second attack after being convalencent from a first attack, and whilst the skin was still desquamating."

A similar case of recurrence, two months after the first attack,

^{*} British Modical Journal, April So. 1856, p. 441.

came under the case of Mr. Elkington at the Birmingham and Midland Hospital for Sick Children." The child, 31 years of age, was admitted on November 224, 1875, suffering from a large abseess in the left thigh. There was a history of scariatinal eruption and sore throat six weeks previously, and the patient was still desquarating. The temperature on admission was 104°, On the 24d the absens was opened antiseptically, and two ourses of thick ereassy pas were evacuated. A draining-tube was inserted, and for the next eleven days all went well, the temperature keeping normal and the abscess closing quickly. On December 5th the patient had benducks, sore throat, and vomited several times; temperature 195". A rush, resembling scariation, was visible on the chest, arms, and neck, and there was great congestion of the throat and toneils. On the 6th the rash was fully developed over the whole body, accompanied by intense thirst and restlessess. Morning temperature 105°, evening nearly 106°, with delirion, From this time the progress was favorable, the rath fading, and the skin desquareating like an ordinary case of scarlatina. On the 13th the temperature was normal.

There are no more obtainate and troublesome supple from any
of the diseases of childhood than those which today searlet fever.
Oterchest and deafness, solarged glands in the neck, ophthalmis,
ozona, cruptions of the scalp, neuto rhomatism, and cheren are
the diseases commonly met with. Hypertrophy of the trouble and
persistent anismis are frequent consequences. However slight the
symptoms may be, troublesome sequence are apt to on-se, and this
is the more likely to happen if the patient quits the sick-room too
soon, or the health has been delicate before the attack.

In 1862 I attended a girl, seven years of age, who was seized with the most severe type of the disease, in which the glands of the neck were greatly implicated, and the delirium was so force and continuous that her life was despaired of. She made a tedous recovery through having an abscess on the right side of the neck, which pointed over the mastered process, and led to exfoliation of the temporal bone. Oterhous continued more or less, and pieces of bone came away. Twelve years clapsed before the local trouble was cured and the wound healed, but now the bearing is perfect and the health re-established after years of extreme medical cure and nursing, which only the wealthy and affluent could procure.

British Medical Journal, April 1st, 1879, p. 441.

My experience leads me to think that tuborculosis can be more frequently traced to scarlet fever than is generally supposed. Of all the sequelse anasarca is the most common,-an infiltration of serous fluid into the subcutamous areolar tissue,-which is proon to occur in some parts more than in others. If, during the period of desquamation, the patient is exposed to cold from incantiously venturing out too soon, and a chill is ressived, the escape of the fever-poison, mstead of taking place through the skin, is directed to the kidners, and this sets up irritation and acute desquamative nephritis. It does not induce this in all, as I have on several occasions seen puffiness of the lower eyelids at the end of three weeks, and swelling of the glands in the neck, whilst desquanation was going on without allowingria. With the kidney affection there is houslache, pain in the loins, sickness and diarrhosa, and a large quantity of albomen in the urine, which may be clear when first passed, or turbid and loaded with mutes. It may vary from day to day, and sometimes contain a considerable quantity of cuyennepepper-looking crystals of uric said; but the albumen may remain muliminished, particularly if animal food is indulged in, or there is any other error in diet. Efficient into the pleaml, pericandial, and abdominal cavities is common, and the temperature is apt to run high." All these symptoms may improve without any diminution in the quantity of albumen."

A serious consequence of scarlation is the headacle of unemin, which I have eisewhere fully considered. At the end of three or four years, and long after every trace of dropsy has disappeared, the child so manifestly declines in health and spirits that the attention of parents is at last awakened to his altered condition. He is unable to pursue his studies at home or to continue at school, and he has no inclination to join in the pleasures of his playmates.

^{*} Wide Chap, XXIV, On Acute Desquarative Nephritis, and (Edeno of Lungs, Chap, XXVIII.

¹ Hardwise, Gold Names, Causs, and Treatment, by W. H. Duy, M.D. 3d edit. Torontic Herdwise, cloip 48.

A severe and continuous frontal headache susues, and the child loss his virusity and interest in everything. The veins are full about the head and lips, in some cases, and there is a set color on the chicks. The urine is exactly and contains albumen, with renal casts and epithelium; it varies greatly in some cases, the deposit theorem down some days being very considerable, and at other times harely perceptible. Indulgence in animal food is prose to cause renal congestion in these cases, with an aggravation of the head symptoms, and there is associated with it semetimes dilatation and hypertrophy of the left ventriele, increased tension in the pulse, perceptible to the finger, but more accurately estimated by a aphygmographic tracing. For the treatment of this complication the reader is referred to the chapter on alluminaria.

Transport.-The treatment of said cases consists in confinement to bed, a mild aperient, and cooling drinks. Rost in bed and julicions nursing will carry most children safely through the attack. With regard to purgutives and active remedies, they have loss inducace over this discuse than some other febrile affections, and the pulse will continue quick, and the temperature high in spite of them. If the howels are costive and the stomach loaded, an active purgative may be necessary. I give preference to purgative remedies, especially at the ouset of the disease. But at the commencement of the disease, and in its early stages, if it is at all severs, the chief indication is to promote a free action of the skin till the child is bedewed with perspiration. If this could be obtained, it would be the best remedy at our command, by favoring the excretion of the merbid poison before it had time to damage any internal organ, and produce them changes in the blood which cometimes lead to fibrinous deposition in the heart. A hot-air hith may be specific constructed, as in group, and it should be soarranged that the child's face is exposed to the pure air, which should circulate freely through the room. In hot weather, during the rising of the fever, free ventilation of the sick apartment is not apt to induce cold, but when desquamation has set in there is great susceptibility.

I am here constrained to point out the value of the action of accuite in reducing fever and inflammation, from the influence it exerts in bringing down the temperature and lessoning blood pressure. From what we know of its power in subdaing fever in some cases of surgical pyrexia it is unquestionably a remedy of great

value, and if we consider the tendency which the blood has to congulate in its passage through the central organ of the circulation, it might be advantageously resorted to in the early stages of this discose. It brings down the pulse, and promotes a free action of the skin, and encourages the less of heat by evaporation. In some cases it reduces fever and inflammation, as in ton-illitis, without promoting perspiration. I fully agree with Dr. Fothergill, that the specific action of accesite is exerted on the vascular system, by paralyzing the vasomotor perves and lessening the contractility of the vessels. If then it has the power of dilating the venels, and by drawing the blood towards them diminishing the tension in an inflamed part, it ought to be employed where this condition is present. All who have given the remady a fair trial in estarch, sore throat, and inflammation of the tonsils, will be willing to admit, that it converts with marrellens rapidity, a dry and burning skin into one that is moist and sweating, and in this way it relieves the rostlessuss and constitutional disturbance. Aconite is of most service and can be more advantageously emplayed when the pulse is hard, and the action of the beart strongand violent. My own experience of the action of acouste is, that it lessens the frequency and increases the fulness of the pulse; it reduces the hardness and incompressibility. Half a minim in a tenspoonful of water for a child should be given every hour, but should the pulse become weak or irregular, or there be any sign of weakness or prostration, it ought to be discontinual. The indiention for giving aponite is elevation of temperature, for where it is present there is fever or inflammation; when the temperature is normal or nearly so, it should not be employed, but when it shows indications of rising, and the palse though not more frequent becomes more resisting, it may be prescribed. During scarlet fever, or after it, when kidney complication has arisen, armite may be given, for if it does not shorten the fever it weether the persons system, and by promoting free perspiration controls the inflammation that attends it, and moderates the throat affection." When the throat is disky and much swellen, and the

It is the default when the acoustic will showen the force of some specific diseases, at senten force, meaning etc., but it has a beneficial influence in these diseases, nonthing the account system, and forceing sleep, by inducing free perspiration. Whether this remedy can be seen the accounty of the force, or distained the duration of the sente specific disease, in declarately; but there is no doubt it can courted and adults the influence type.

symptoms assume a typhoid character, aconite would be too depressing, and the local disorder is best treated by the application of nitrate of silver or the diluted tineture of the perchloride of iron, Internally, the iron and chlorate of potash mixture recommended in diphtheria will be found invaluable. (Form. 54.)

Some years ago Dr. Richardson advecated the value of liquor ammonia, from its power in holding the fibria of the blood in solution, and keeping it in a finid state. A few drops of the Liquor Ammonia in water, with or without the addition of the Liquor Ammonia Acctatis, is the form he recommends to be given. Both these remedies tend to eliminate carbonic soid by the breath and skin, but they require caution in their administration, lost the free ammonia interfere with oxygenation, and break up or damage the red corresples of the blood.

In Scorlation anythose, if there is reason to think the digestive organs are leaded, and the tongue is heavily furred, an ematic should be given at the oract. A grain or two of calonel and an active aperiout may be ventured upon, if the pairs is full and strong, and the inflammatory fever runs high. Milk and sola mater to drink frequently, ice to suck, beef ten and chicken broth will be domanded. Warm lineard positions, or even two or three leaches, to the throat will be advisable, if there is swelling about the juwa or pain in smallouring. Effectivening multicines, such as earlients of ammonia and leasen-juice, are refreshing and agreeable to take

Sponging the holy with vinegar and tepid water (one in four), or icod water, if the temperature runs high, should be practiced three or four times a day. I prefer this milder practice to cold effucious, or cold wet packing, which, so far as my experience goes, are only to be adopted in exceptional cases. The treatment by cold water has proved curative in this variety of scarlet fever when cerebral symptoms are present, and come threatens; no other numely except cold having the power to reduce the hyperpyrexis, as in those cases of rheumatism, where a dangerons rise of temperature takes place." This plan should be adopted when all other

affection which often accompany them, and which, by their severity, may enlarger life. They armite will another he meither greeces our election the course of the inflamountoe of the threat in souries fover, and the cutarrh and bounchitis in meader, and in the inflavor measure lower the height of the fover,—Dr. Diagor's Hamilton's of Thorspectics, 4th offices, Actions, p. 485.

^{*} See Class XLIII, "On Acare Bleamilian."

remedies fail, and the skin is extramely hot, the pulse fail, and there is drowsiness, convulsions, or delirium. It is better to immerse the patient in topid water first, and gradually cool it by the addition of its. The effects of the bath on the temperature should be excefully watched, the patient not being kept in it for more than ten minutes at one time. If there is delirium and a tendency to count, the scalp may be shaved, and cold lotions applied to the head. In this form of the disease, depression soon sets in, and port wine, beef ten champague, and asla-mater will be required.

For the throat affection, if the patient is old enough to manage it, a gargle of chlorate of potach and dilute hydrochloric acid will correct the unhealthy excelation that hangs about the throat, but in the case of very young children this cannot be used, and then mapping out the fances with a solution of nitrate of silver (gr. x to the 5j) twice a day will be effectual in most mild cases, or a weak solution of chloriented sodn may be substituted.

The inhalation of the steam of het water as long as the threat is sore, is a safe and excellent practice, and according to Dr. Gairdner, expersedes almost all other local applications.* The inhalers used for this purpose, however useful and easy of application for solubs, are somewhat alarming and difficult for very young children. The steam draft inhaler brought before the notice of the Medical Society of London, by Dr. R. J. Lee, is well adapted in these cases.*

When the exudation is of an usby color and inclined to extend, the solution of perchloride of iron, applied on a sponge with forceps, will exert an excellent effect. It should be used night and morning at base, and after two or three applications, the throat will assume a more healthy appearance, and the fotor of the breath will diminish. In very young children, it is necessary to apply the solution lightly, and to limit its application to the discused surface, for if any roughness is employed, and great care is not taken, the healthy parts are irritated, and the soreness and inflammation increased. The diluted solution for children is generally slrong enough; but this may be left to the discretion of the

^{*} Choicel Molicine, Southt and Caterio Fever, p. 1984.

[|] Molical Society Proceedings, vol. 1v, p. 201.

L Foresta Ma

practitioner, as where the throat is dark and much implicated, I should not hesitate to employ the pure solution (Liq. Ferri Perchlor., B. P.).

In cases, however, where the jaws are stiff from the swelling, or the shild resists obstinately, or is exhausted, it is perhaps better to desist from local interference with the throat. If a case of this difficulty presents itself, the carbolic acid spray is one of the best applications. When foul secretions collect about the faures, and cannot be thrown off by any efforts of the little patient, the spray ought to be employed. In both chanses and disinfects. As it is of the atmost importance that the patient should breathe as pure an atmosphere as possible, it is evident that if the air becomes contandnated before it reaches the longs (as it will do if the threat is covered with decomposing accretions) the child's life is placed in still greater jeopardy. The valcatite spray producer, as sold by surgical instrument makers, is of great service in all inflammators or irritative affections of the throat, larynx, and brought. It is easy of application, and causes mother pain nor inconvenience. The vulcanite and must be introduced between the teeth and above the tongue, because a young child will not open its mouth when bid. They with gentle pressure on the hand-bull, a stendy and uniform stream of carbolic spray can be kept up and maintained, if compression is made about once in every second. It nots directly on the diseased tissues, and gradually penetrates deeper than any gargle or other similar mode of application; causing neither pain nor irritation to the inflamed and sensitive threat. I give preference to carbolic acid, but other medicinal agents may be used. In cases of throat affection due to the examthemata, I have seen excellent effects follow the use of the spray vaporizor-the respiration and the power of awallowing rapidly improving, and patches of slongh and exudation expectorated. In young children I have on several occasions known life sayed by it, and it is a remedy to be held in remembrance. Three or four inhalations may be used a in the space of twenty-four hours, and the strength of the liquid may vary from one in twenty to one in forty. For fear of fatiguing the child, each application should not exceed three or four minutes. Soon after its use, I have known a child, previously on the verge of come and breathing rapidly, wake up lively, and from that time improve, till a repetition of the same application was demanded by a relayee of the symptoms,

Meigs and Pepper recommend a decoction of strong green ten and alum, or sage ten and alum, or lime-water, or honey of roces and torax." Sir T. Watson a solution of chloride of solu.† Dr. West one part of hydrochloric acid to six parts of honey, by means of a dessil of lint or a camel's-hair brush, two or three times a day.‡ For the coryza, any of the astringent washes used for the throat, or a solution of nitrate of silver—gr. j or gr. ij to 3j of water, thrown up the metrils every four hours.

In Senisting unlight the treatment must be of a supporting character from the first, and ammonia, bark, iron, | port wine, and brandy are required to be given freely. There is here a tendency to failure of the heart's action, either from delelity and exhaustion,

or from fibrinous deposit in its envities.

Sir Thomas Watson recommends in scarlet fever a chlorine drink, now well known to the profession. It is composed of eight grains of chlorate of potash, one drackm of hydrochloric acid, and one pint of water. A child ten years of ago may have it rather more diluted, and take half the quantity during the day. The chlorine possesses disinfecting properties, and the solution renders the foul sarrations which collect upon the fances loss noxious and hurtfel, and the tongue becomes clean and moist. Or the following mixture may be used: Put an onnee of chlorate of potash and the juice of two moderate-sized lemons into an ordinary wine bottle, and fill up with water. A wineglassful may be given, or taken, two or three times a day by the patient and by those in attendance.

For the dropsy that follows scarlatina, warmth and a milk dist are to be adopted. An occasional aperient of compound jalap powder in the morning, and small doses of tincture of digitalis with nectate of potash during the day should be given, if the trine is scanty and high-colored, or contains any blood. If there is pain in the loins, a vapor-bath or a position, applied every night

should be employed." When the urine is clear, though albuminous, and the febrile symptoms have departed, the tineture of perchloride of iron (Form. 53) should be given, and if the child loss flish, and there is no sickness or discriben, coddiver oil will be a useful adjunct. For the efficient that are liable to occur to the pleural or pericardial cavity, discretice and toxics are to be our ployed, and all those remedies which encourage the action of the excretory organs, and improve the quality of the blood at the same time. When an attack of scarlet fever and its consequences have passed away, the patient should wear flamed next the skin, and go to the masside for change of air. However well a child may be going on, after a severe case, a month or six weeks ought to chapse before it goes out of doors, and even then the weather should be considered.

For many months after an attack of searlet fever, and it may even be for an indefinite time, there will be observed in some eases, reperially those marked by natemia, a faint and peristent trace of albaneau, with an other morbid change in the urine, as take casts or recal opithelism. This condition attakens some anxiety, though it may continue for twenty years without any manifest impoirment of the general handth. When attemnia is present, I strongly advocate the steady use of the functure of the perchlorate of iron, and in some instances, where recal congestion is easily provoked, the addition of gr. 2, of perchlorate of merenry three times a day. When the diet is carefully regulated and cold avoided, perfect recovery may take place, but there will be so chance of this, unless stimulants are prohibited, and milk and white fish take the place of ment.

Now, as to some precautionary measures in arresting the spread of this disorder. Isolation of the patients suffering from searlet fever is one of the chief circumstances to be horse in mind in order to prevent its extension. The apartment in which the sick pressu

^{*} See Chap, XXIV, "On Jorns Despinantery Nephritis." In the Pengillimet list August, 1976, Dr. de Havilland Hall has recorded as interesting one of acute despairables replacts following service fever, in which the patient, a last size years of up, prood no water for fifty from other admission, and from his incline's account very brite had been proof previously. The entire alsonate of any of the symptoms of uponin in the case was statistical in part to the last that all anishes of accordance, except a little milk and a free supply of water, more withhold. The only medicinal treatment was a done of Pulis, Julepin Co. and a drawful of historiests of potacities a drink.

is confined should be well ventilated, and curtains, carpets, and all unnecessary articles of furniture should be removed. The bed linen and that worn by the potient should be changed daily, and placed at case into a deep common hip both, under water, so that the desquaunting epidermis may be less likely to propagate infoction. I recommend a weak solution of carbolic acid to be thrown into the both, and two or three squeers containing it to be put in the sick-recon and various parts of the house. I also insist on the importance of adding disinfectants to the evacuations, and getting rid of them directly. With these precautions I have often known the discuss not to spread. Infection persists so long as there is the least trace of desquamation, and to insure safety, is cation should be enforced for at least a week after the last particle of exfelinted enticle has been detached.

Dr. Wm. Budd's" directions for limiting the spread of the disease are well known to the profession. His paper is so full of interest, and his directions so eminently practical, that I shall quote the chief precautions which he enforces.

 Theorem is to be dismantial of all needless weedless or other draperies, which might possibly seven to harbor the poison.

 A basin charged with chloride or carbolate of time, or some other convenient disinfectant, is to be kept constantly on the bed, for the patient to spit into.

3. A large vessel, containing water impregnated with chlorides or with Condy's fluid, should always stand in the room, for the reception of all hed and body linen immediately on its removal from the person of the patient.

 Pocket handkershiefs are prescribed, and small pieces of rag are used instead for wiping the month and nose. Each piece after being once used is to be immediately hurst.

- 5. As the hands of numes of necessity become frequently sciled by the specific exercts, a good supply of towels, and two basins, one containing water with Condy's fluid or chlorides, and another plain soap and water, are always to be at hand, for the immediate removal of the taint.
- All glasses, caps, or other vessels, used by or about the patients, are to be scrupulously cleaned before being used by others.

^{*} Scarled Peters and the Pressurion, Brit, Med. Journ., 1869, vol. i. p. 35.

 The discharges from the bowels and kidneys are to be received, on their very cone from the budy, into vessels charged with disinfectants.

Dr. Build considers that by these means the infectious power of the germs is distrayed as they emanate from the skin, the surface of which is so extensive, that the poison escaping by it is far greater than that which is cast off by all the other surfaces of the body combined. An impalpable powder armed with the subtle poison of searlet faver, floats in the atmosphere and conveys infection to any person who may be within the sphere of its influence. To provent the escape of these particles from the body and earrying the poison for and near, Dr. Build strongly advises anointing the body and scalp with olive oil impregnated with camples twice a day. As soon as the skin begins to ped (and this is sometimes as early as the fourth day) the foling should be commenced, and continued till the putiont is well enough to take a warm bath, when the whole body and head abould be well serubbed with disinfesting soup (Calvert's or McDonghall's). The baths are to be repeated. every other day until four have been taken, when, if the patient has now clothes, and there is no throat or kidney complication, he may return without risk to his family in a week or ten days. After this the sick-room should be well fundanted, and the bedding or curtains exposed to a high temperature (240° or 250°), which is said effectually to destroy the power of the specific poison. The principles advocated by Dr. Budd apply to all contagious fevers, as small-pox, measles, typhus, etc., and the method employed has proved so successful in his hands, that, during a period of twenty years, he had not known the disease to spread beyond the sieloroom.

"Hanging rags stroped in disinfectant solution about the room
is not to be connected, but a sheet moistened with a strong solution of chloralum, earbolic soid, or Condy's finid, and suspended
outside the door of the room, is very necessary to complete the
isolation of the patient. . . . Care must also be taken in using
different disinfectants that they do not counteract each other; for
example, carbolic acid decomposes Condy's fluid."

The prophylactic powers of beliadonna, which have been caunted for preventing an attack of scarlatina, are so funciful that I do not attach importance to the statements that have been made in favor of it.

^{*} Hardlook of Hygiens, by Dr. Wilson, second edition, 1873, p. 304.

SMALL-POX is a highly contugious febrile disease, following a definite and uniform course, which after a latent period passes through the stages of pimple, reside, pastule, and scab. Since the introduction of vaccination this disease has become comparatively rare; and if this preventive measure is efficiently carried out there is every reason to hope that it will gradually become exterminated. In this country it is compalsory to enecimate by the third month, and as very young children are especially subject to the disease, and it spreads with alarming force, the law cannot be too stringently observed where the health is good. Older persons who have been successfully vaccinated are in a great degree exempt from the disorder, and they may enjoy immunity from it if revacrinated when growth is completed, or when an epidenic prevails. When a person who is unprotected by vaccination is exposed to the contagion of small-pox, he may contract the most malignant form, according to the state of his health and the type of the disense that prevails. Three varieties of small-pox are usually described:

- 1. Varieta discreta, or distinct small-poir.
- 2. Varida conflants, or conflant analysis.
- 3. Variela hemserhagian.
- L. Variola discrets, or the milder type, has three stages like

other exambomatous affections. (1.) The stage of incubation. (2.) The stage of dramation,

L. The Shope of Jacobarlea, .- Fourteen days usually shaper in turner the time when the poison is received into the system and the appearance of the scuption." Two days preceding the cruption the constitutional symptoms are marked by a rigor, sovere headache, less of appetite, and thirst, but they are sometimes overlooked, and in a few instances I have seen children brought for an opinion about the character of a small pox eraption which correct the face, and caused but little derangement in the general health. There is usually the history of a day's malaise before the spots appear, and where a child is seen during this doubtful period, there is always such rise of temperature as warrants rest in hel, and a cautious diagnosis. Generally some symptoms of gastric disorder precede the outbreak of the exauthers, as a thick-coand tongue, romiting, and irrogularity of the bowels; pain in the back and loins, constantly observed in adults, cannot be ascertained in young children, as if the question is put they are cortain to complain of it. At this time the accompanying febrile excitement is always shown by the clinical thermometer. Then disturbances ensue in the normus and enscular system; the skin fods hot and pungent, and there is healache and restlesiness-healache is a constant and severe symptom. Sometimes there is delirium or convulsions, and a torpid or even comato-s condition, from which it is not easy to rouse the child. The palse is quick and full, 19) to 140, and towards evening the febrile exacerbations become greater, and the temperature rises to 104" or 105", the eres are suffused and heavy, and then the eruption makes its appearance, which occurs earlier in severe than in mild cases. Sometimes a resectors rash precedes the characteristic cruption, which has received the name of "rosesia variolosa," and then it may be impossible to diagnose it from membes.

The cruption first shows itself on the face, in the form of small " red elevated popules resembling measles. Soon an elevation takes

In three cases mentioned by Dr. Marchison, the invalidition-period, during from the time the pole-in entered the system till the fact symptoms appeared, was thirteen days in two cases, and picture days in one case, on that the latent period is subject to varieties, so it is in all of the infermious theorem. Of eightons cases, the above involves appeared was into days in one case, glower days in five cases, and thirteen days in one case. Observations on the Period of Rapidanion of Spatist Fever, and of some other Decease, Clin. Trans., 1878, p. 250.

place in the centre by the development of a small tuberele, and by the second day, it attains the size of a pin's head, and impurts a feeling of small shot to the finger. On the third day, it is as large as a lontil and extends over the rest of the face and ucek, to the shoulders, trunk, and extremities. The cruption is darker and most abundant where the parts are exposed or uncovered, and on protected parts, as the body or feet, it is of a light rose color. About the fifth day, a small vesicle containing a clear fluid forms on the top of each piople-it is tense, like a small blister, but soon becomes depressed in the centre, with an inflamed arcola or has surrounding the elevated pingle. All the points, or papules, do not pass through the same process of change, as some of them never reach the stage of maturation, but pass away in the course of a few days, especially on the legs and feet. The excitement and inflammatory fever new quickly subside, the pulse is reduced in frequency, the secretions become more natural, and the cerebral disturbance passes off. On or about the sixth day, there is soreness and smelling of the throat with difficulty in swallowing, and the rash and small circular white spots may be seen on the finces. This does not occur in all cases. The throat is sometimes free, though the attack is a severe one. The face and syelids swell, so that the features of the patient are no longer to be recognized. On or about the eighth day, the central depression disappears, and the contents of the vesicles become purnlent, the redness of the arcola is more extensive, and the face more swelled and bleated." In cases that pursue a satisfactory course, a brown spot forms in the centre of the postule, which attains its full size by the ninth day, the arcola around the base becomes less inflamed, and the puffixes of the features disappears. At the same time the face and hands begin to swell. The pustules now rupture and the essage of their contents dry up into scale, which fall off in the course of four or five days, beneath which the skin is of a pur-

plish color, which lasts for a considerable length of time. The bursting and desiccation of the pustales begin first on the face. and gradually you downwards to the trunk and extremition. Something the surface prevents children from giving the pastules a chance of drying up without bursting. The swelling of the hands and feet passes off, and the patient is convalescent by the seventeenth or eighteenth day. If the case is a severe one, and the child has not been vaccinated, a permanent depression or sour is left in the skin marking the situation of each pustule. This becomes covered with a new spidermis, and the cicatrices appear very marked in children, but as they grow older, the skin being thin and clastle, the depressions are not so apparent. About the eighth day, when the vesicle has become pustular, a secondary or suppurative Sever appears; the face is more excelled and inflamed, the pulse is quick and weak, the torgue inclined to dryness, and the temperature considerably elevated.

The urine is scanty and high-colored and the bowels constipated, so that the little patient becomes restless, or even debrious at night; the surface itohes to such an extent that the whill scratches and team open the pustules unless the greatest prometions are taken.

2. Variable tooffuces or Confluent Small-par.—This variety of the disease is more severe than that just described. It sets in with more severe rigors, with fever, headache, and delirium. The secondary fever is also of a typhoid character, and there may be come and justitation. The rush does not appear with the regularity of the milder affection; a red crythematous blush appears on the skin, and on the second day, small red points may be seen, and the postules are not distinct but run together and are flat. They often contains thin, brownish, ichorous discharge, instead of puralent matter. The cellular tissue beneath may be involved in severe inflammation and sloughing, and the swelling of the face and salivation begin early in the disease. The secondary fever is much more dangerous than in the first form, and quickly assumes a

^{*} The imputey constitut in the compline and supportative stages may contain trains of allowant, which indeed is common to those periods in some other of the constlements. Receptoral states that it is moratal during desegmention, but in the partial near of the discuss. * It is decomposed and managinal," and may constitute contain bladd. But this is simply due to the homotoria, which we have some to be common when the points is of a very emligatest character, and is past of the same condition which produces each morate of the conjunctive and petechine on the skin.

typhold character. The cruption is dark and livid, and petrolize are common, as well as hemorrhages from the uncons surface of the bourds or bladder. The exhaustion increases, and the patient perhaps dies convulsed, or in a state of coma. In cases of recovery the cicutrices are deeper, and the deformity greater. In one case of extreme severity that came under my care some years ago, the outline of the ness was completely efficied, and the cyclids infiltrated with serum and covered with pustales. The fauces, month, and nose were similarly affected, and the tougue was so swelled that it could not be retained within the month. The neck and cervical glands were avoilen, and viscid surva was constantly pouring out of the month. This distressing condition had only lasted a few hours, when, in making an ineffectual attempt to swallow a little-fluid that had been put into the month, the patient was seized with sufficultive symptoms, and died instantly.

3. There is yet another variety termed Varials Assurvingsica for Mark mostlyway, which is occasionally mot with in severe epidemies. Beight red petechie oconr upon the skin about the size of a pin's head coincident with the appearance of the papules, which become darker and of a purple has on the third or fourth day of the disease, when a spot of purpum or of hemorrhage occupies the pastule. White pastules may be seen on the fances and palate. Hamorrhage from the mucous surface of the vaging, bowels, and urinary passages (Incunaturia) distinguish the disease. The mind is collected, and death occurs on the third or fourth day of the disease. Congestion of the chief internal organs is seen in the lungs, mesenteric glands, and spicen, and ecclaymoses, like the patechie on the skin, are scattered over the intestines. Soft clots are found in the right side of the heart, while the left is empty. These cases are rare, but they occur in every severe epidemic, and when once seen cannot readily be mistaken, though they may be overlooked, in consequence of death happening before the rash is well developed.

Variated or satisfied analy-pax is the term used when the disease happens a second time, or the patient has been protected by vaccination. The fever lasts only a day or two, and the sruption appears in the morning, the general health being slightly deranged the day before. A few scattered pimples appear on the forehead, face, and nose; some of them become voicies, and others shrivel up, whilst on different parts of the body they present various stages of imperfect development. The rapid fall of temperature on the second or third day as the rash appears, distinguishes it from typhus and from measles. Unless the rash is extensive them is no secondary fever.

The cause of small-pex is due to a specific poison from a person laboring under the disease, or from clothes left off by the sirk and worn by the healthy. It is conveyed by the atmosphere and is enught from vehicles in which diseased persons have ridden. It may be communicated by inocalation or by the scale from the sick. "Most likely it is communicable from the moment when the initiatory fever begins. It may be given by the breath of the patient before the eruption has appeared on the surface of the body. It continues infectious so long as any of the dry scale resulting from the original eruption remain adherent to the body; a single breathing of the air where it is, is enough to give the disease. The dead holy for several days after death, has been known to communicate the disease, and in all probability it would produce the disease for some menths afterwards."

Small-pec scidom attacks the same person a second time, not one per cent, being liable to a recurrence of it. The disease may attack the fectus in utero.

As to the prognosis of the disease, it is favorable in the vaccinated, if three or four good vaccination-marks remain, if the disease is mild and distinct, and if the children are strong and healthy. It is unfavorable if vaccination have never been performed, or if there be only one or two faint marks of a single raccination; if the symptoms assume a confuent form, and the purtules are dark and flattened. A sudden disappearance of the rach, with prestration of the strength, and a rapid feeble pulse, are indications of danger; and where they are present the typhoid state continues, and leads to death by syncope, convulsions ar coma. Inflatomatory affections of the brain, pneumonia, and suppunction of some of the viscera, are among the modes of fatal termination.

Doubt most commonly occurs in small-pox after the primary fever, and seidom before the twelfth day—the most frequent complications are meningitis, and affections of the thornele organs, severe diarrhous, and lesions of the intestinal canal, and, according to Vogel, gangrene of the mouth is sometimes present.†

^{*} Reynoldr's System of Medicine, rol. i, 24 wdh., p. 242.

Diseases of Children, p. 491.

The mortality from this disease increases with age; while it is very fatal at the extremes of life.* Much will depend upon the age and constitution of the obild, and whether it has been previously variented or not. Where it is neglected, the child gets a severe attack, and, if it recovers, bears through life the most disfiguring cicatrices. In the once of a mother and child, who cause under my notice some years ago, the former, who was protected by varcination, had only a few small spots on her face, and made no complaint of her health beyond elight institude and disonlered digestion; whilst the latter, who was four months old, and suckled by the mother, had her face covered with the emption, and the body and limbs were also much involved. The child recovered, but to this day the face is frightfully pitted by the numerous ricustrices.

Of the morled appearances found in those who have died of small-pox, evidences of inflammation are met with in the intestinal caral, the bronchial tubes, and various parts of the brain, in consequence of a deteriorated state of the blood, which is found liquid, dark, and uncongulated. Universal congestion of the internal organs is also present, and the liver, spicen, and kidneys contain a great deal of blood. The brain and membranes are congested, and the sinuses full of blood. Pustules or false membrane may be seen in the mouth, tongue, fances, and pluryux, and throughout the asophagus to the rectum, beneath which the membrane is inflamed and vascular. Evidence of inflammation in the interior of the heart and pericardium is also to be noted, and a change in the muscular structure leading to granular or fatty degeneration.

Frontiers,—There is no discuss in which it is more necessary to keep the apartment roof and ventilated. In the winter senson of the year there should be a fire in the room, and the windows opened from time to time, and so managed that the patient may not be exposed to draughts of cold air. In the summer, when the weather is but or sultry, the windows should be opened at the top, and curtains and excepts be removed. Disinfectants, in the shape of tarbolic arid, Condy's fluid, or chloride of lime, should be placed in sources and put in the room and passages of the house. All these important precautions ought to be streamously enforced.

Before the cruption makes its appearance the treatment should

[&]quot;According to De. Marson, patients of all ages die at the rate of 50 per cent, in the confluent, and 5 per cent, in the semi-confluent, and 4 per cent, in the discrete earliery,"—Hospier's Physician's Viole Money. Dr. Gay and Dr. Harley. Article, Variota, p. 200.

be directed to moderate the fever and subdue the nervous excitament. To attain this object an enotic may be given, followed by a mixture of sulphate of magnesia with nitrate of potash (Forms 8), or infusion of some, to control the fever and open the bowds freely. If the child is strong and there is constipation a grain or two of calomel, followed by a draught of sulphate of magnesia and some, should be ordered. In mild cases a dose of caster oil, or a draught of rhuberb and magnesia, will be sufficient to clear the bowels of any irritant matters.

If the discuss happens in hot weather, and there is much thirst, and soreness of the throat in swallowing, weak tea and milk with toast will be sufficient neurishment for a day or two, and grapes, strawberries, and ired lemonade may be taken freely. Raspherry wiregar is an excellent drink and relished by all parients.

During the period of eruption and maturation the measures to be employed are much the same; and, if there is restlesaness and irritation of the skin, it is a good plan to use a warm both, to which carmed or carbonate of sods is added. If itching and irritation of the face are severe it should be ameared over with olive oil, or clive oil to which earbolic and (1 in 40) is added, or give erin, or zine sintment. Pork lard melted in a saucer and applied to the face allays irritation in a remarkable manner. If the strength appears deficient it must be supported by suitable nourishment, as beef ten, chicken broth, and so forth. When the fever subsides a stimulating disphoretic may be given." If the child is restless at night beomide of potassium or hydrate of chloral at bedtime should be employed, for if the patient cannot obtain sleep he will become exhausted and the restlessness will increase. Opintes, however, must be used with great caution. For the delirium which arises in the course of small-pox, care should be observed in noticing whether it is due to a pletboric state, with a full pulse and active

coroleal excitement, or whether the child is weakly and delicate, and the pulse quick and running, so that each heat is not appreciably distinct. In the former case cold spanging or ice to the head may be required; in the latter case stimulants and nearishment, with quinine if the temperature be high, are the only remedles to subdue it.

Local inflammation must be treated on general principles, Where collections of matter form, whether in the cellular tissue or under the scalp, they should be opened early to prevent their spreading, and cavities may be washed out with carbone acid totion (I in 40) or nitrate of silver (gr. x to the 5). The discharge from the pustules in severe cases is very irritating and canons much discomfort. To meet this the linea cannot be too frequently clanged, and oxide of sinc and starch in equal proportions, or calculate possiler and oxide of zinc, or floor, or some of the toilet powders in use, may be dusted over the body from a common dredger. For the romiting, which sometimes occurs, iced water or prussle acid is useful; and if the child is old enough an effervescent mixture, and a positive to the epogastrium. If the threat is much swotten two or three leeches may be applied, and afterwards a position. Mosping out the throat with a weak solution of nitrate of silver, or the infusion of roses with sulphuric acid, is also to be recommended.

Boils frequently result from small-pox, and they are tedious to heal. The discharge exhausts the patient and prolongs his convalencese. When this complication has arisen quinton and barkuill be required to support the strength. The naneral arids with tincture of gentian often answer well, and the wounds should be dressed with some stimulating continent. If sloughing takes place a carrot or a linseed poultice should be applied, and the free use of carbolic acid or Condr's fluid should not be omitted.

When the emplies force has passed away, and there are languor and clammy skin, the mineral acids with bark or calumba will be serviceable.* When the strength begins to fail tonics and stimu-

lants will be needed. Quinine and ammonia are the best, and wine and brandy according to the exigencies of the case.

In the hemorrhagic variety of the affection, the free use of stimulants, and supporting measures of all kinds are demanded. In the shape of medicine some styptic preparations of iron, as the freeture of the perchloride, should be given to restrain the hemorrhage.

When diarrhora is excessive it should be checked by krameria,

small doses of lambanum, so the Pulvis Crotic c. Open+

The prevention of pitting is no ineignificant part of the treatment. The parts affected, particularly the face, should be protected from the nic, and the lymph let out from the distended resides by a needle, and absorbed by cotton-wood. The top of each pastule is to be lifted up, and a thin point of nitrate of silver applied to the base. The remedy to be successful should be applied on the second or third day of emption, and, though it causes some pair, it soon passes off, and diminishes the swelling and tamefaction of the pustules, and prevents cicatrices. Of the application of mercurial cintment to prevent pitting, Rilliet and Earthez state, that it was successful even in cases of confluent small-pex, and that when applied on the first or second day it prevented the development of the emption, and caused an abortion of the pustules. To protect the skin, collection may be applied, or, still better, the flexible collection made of collection, castor oil and Camada Indean.

The plan adopted at the Small-pox Hospital is as follows:

"Wait until the pastules have discharged, and the discharge has begun to day, then put on some of the best olive oil, or a mixture of one-third glycerin and two-thirds of rose-water. Some of this may be applied once or twice a day, for a few days, until the scale login to locous. Cold oream and oxide of zing, or clive oil and lime-unter, form good applications; or if the discharge is

thin and exceriating, calamine mixed with clive oil. The patient should be married not to allow the scale to dry and remain some time on the nose and other parts of the face, particularly on the forchead and mear the end of the nose. When this takes plane, the dry scale themselves leave deep marks in the skin, werse than the eruption of small-pox itself. The pain of removing the dry scale is sometimes considerable, and the patient can hardly be prevailed to take them off, or allow others to do so. In common the pits from the eruption are not deep at first, just after the patient has got well, and we may decrive correctes by thinking our efforts to prevent disfiguration have been attended with considerable streets. The disease leaves a peculiar brown stain on the skin at first, which soon wears off, but the pitting is more perceptible a twelvementh or so after the patient has got well."

If opithalmia is severe two or three leaches to the temples may be necessary, and in milder cases a solution of nitrate of silver (gr. j to gr. iv to the 5)). When the epclids are swotlen and edematous, and the lips stick together by a templess secretion, they should be hathed frequently with warm water and a little Ung. Cetacel, or diluted yellow oxide of mercury continent (Hyd. Oxy. Flava gr. viij, Vaseline 5j) applied to the edges of the cyclids right and morning. When alcorations of the corner cases, it has been recommended to touch them with a sharp point of nitrate of eliver, or a collyrium of sulphate of zine and opinm may be used. Theirs and Pepper speak highly of a collyrium of borns and sul-

phote of zinc.;

CHAPTER XIII.

DISPLICES OF THE MOUTH AND PAUSES.

Sendantin and its Variative Sometics singues, or made information of the most Sometic Constraint Sometic policy of the most support of the most su

Ixrammation of the mouth is a troublesome and painful disease in infants and young children. Although extremely common during the period of deutition, it may occur at almost any ago. In one variety the inflammation does not extend through the america membrane, or, at the worst, it produces a number of small, circular, irritable ulcers, with a red margin surrounding a depressed centre, whilst in mosther the ulceration involves the guns and the mucous membrane more deeply, and in a third, swelling and gaugiene attack the cheek, and destroy the life of the authore.

Syssalide chapter, or inflammation of the mouth, is a mid affection, entring trilling constitutional disturbance, and, except under neglect, rarely leading to ulceration. It is common among the infants and suckling children of the poor during the first year of life, involving a portion, or sometimes nearly the whole mincous membrane of the mouth, particularly if the food is taken through bettles and the hygienic conditions are bad. It is rare among the children of the apper classes, unless the nipples of the nurse are sore, or the milk is faulty. In the out-patient department of our hospitals it is very frequent. In its mildest form it is an crythema, but occasionally minute vesicles are seen on the affected numbrane, and the lips swell with an herpetic eruption upon them. Sometimes the salivary glands are very active, and salive dribbles from the mouth. The semptoms are heat and dryness of the month, restlessness and feverishness, flatalence and diarrhou; the murous membrane presents patches of relaces

raised above the surrounding surface, which are seen on the inside of the cheeks and the angles of the month; they may also be observed on the hard palate and gams, having a yellowish patch of truth in the centre, with a red margin.

The causes are gustro-intestinal disorder and uncleasiness, and eating indigestible or irritating articles of food. It is seen in scariatina and measles, or during dentition, when the guass are irritated by the pressure of teeth, and then the disease is local instead of general. In these cases the guass are often red and

spongy, and bleud on being touched.

The disorder usually yields to a regulated diet, a dose of castor oil, or a powder of rhubarh and carbonate of soda. If it does not improve under this treatment, a mixture containing a little magnesia, or the Liq. Magn. Carls will be useful. Lincowater should be added to the milk, and the mouth cleaned after each usual with a piece of soft rag dipped in warm water. If the guns are swellen and distended by the teeth, they should be lanced. Occasionally the disorder is kept up till the nurse is changed, and the method of feeding is altered. In one well-marked and obstinute case which cause under my notice, the mouth did not take on a healthy appearance till feeding with a spoor was substituted for the bottle and the nurse.

Stomatiks followings (resicular stomatics—splittons accounts) is common with children during the first dentition. Large and distinct partilike vesicles of a round and elevated form resembling herpes, take place on the inside of the checks, lips, sides of the tongue, and more rarely on the game. When they rupture, a little glairy fluid is discharged, leaving a round and superficial after with a red margin and a yellowish-gray base. The complaint arises from inflammation of the mucous follicles, symptomatic of some intestinal disorder and acidity of the primar via. It accurs during teething, or after whooping-cough or measles, in fact, it may follow any exhausting complaint. There are several of these alcers which do not usually run together, except the disorder is severe; and although most frequent on the mucous membrane of the check, they are sometimes noticeable on the tonsils and soft palate.

Symptoms.—The constitutional disturbance is slight, and there is nothing to notice beyond trifling feverishness, loss of appetite, thirst, and irritability; sometimes there is not even this assemblage

of symptoms, and the chief feature is pain with sorccess of the mouth, which prevents the child from taking nourishment. The complaint is of common occurrence in delicate children, and is without danger. The olcurs pass away under treatment in the course of a few days, but are prose to recur from time to time, as in adults when the digestive functions are deranged. It is important to lear in mind that the disease does not always follow the same mild course. After the bursting of the vesicles the superficial abscration that remains may be cented with a similar expulsion to that which occurs in thrush, and to be even associated with the formation of false membrane, as in diphtheria. Such cases sensitions follow nevers attacks of naturales.

Treatment.—An alterative dose of gray powder, soda, and rhabarb is useful, and touins—bark, with a few grains of chlorate of petash—will being about a cure. If the mouth is very painful, and prevents the child from taking food or sucking, a weak soution of nitrate of silver may be brushed over the exceptated parts thaily, or they may be touched with a piece of alum; a lotion reasisting of one course of glyceria of borax to five ounces of water is also a simple and useful application.

Stemantis Fungous - Aphtha Undergood and Dences - Le Muquet (French - Thrush or White Mouth Diffice Individuation of the Mostl. - This complaint is met with at all ages, but it is most common in infants and young children, as the result of improper or artificial feeding. The mouth is not and dry, and the salivary acretion is diminished. Small white conical patches form on the inside of the cheeks, angles of the mouth, and sides of the tongue. After two or three days those elevated patches present a cards or soft cheesy exudation of false numbrane, and may be seen on the plarynx, tousils, or hard pulate, and if removed the surface bloods until it is covered by fresh exudation. The patches assume a grayish ragged appearance, leaving an unbroken smooth surface, or a superficial excertation, which increases the difficulty of swallowing and sucking. The disease may extend into the anophagus or the air-passages, and cause cough and expectoration, which reduces the child's strength, and may end in exhaustion and inamition. It is most frequent in infants of two or three months old. The constitutional symptoms are gastric disorder and diarehora, with all the symptoms of muco-cateritis; the motions are greenish, mixed with cardy masses of milk, and in this way the disease extends

through the whole alimentary tract. The anns is often red and excoriated from the acrid nature of the Issuel discharges, and there is crythema of the buttocks and perincum of the child, and if of the male sex, the acrotum is sore, exorciated, and inflamed. Febrile excitement is not uncommon, and the pube is accelerated. It occurs in delicate children who are hadly fed and clothed, and is looked upon as a serious sign; but it is simply the local indication of a feelde constitutional condition. It comes and goes, and when seen as the accompaniment of acute or long-standing chronic disease, is of evil angury. The explation has been seen in the stomach in Poyer's patches, and in the cocons "Under the microscope the curdy exedation of thrush has been found to consist of thickened epithelium cells, mingled with numerous minute reyntogamic sporules or sunds, from the midst of clusters of which, long threadlike, jointed, and branching plants arise, intertwining with one another. It was discovered by Berg, of Stockholm, and Grule, of Vienec, at the same time, and has been named the Oldran officers,"a

Like the former variety, it is chiefly mer with among the children of the poor, and those brought up by hand or suckled too long.

The predisposing causes are attributable to general or local discase, but the exciting cause is owing to a parasitic fungus, as we have just seen in the mucous membrane. This regetation is probably derived from some moubly article of diet, which may spread and be conveyed to the nurse's nipple, and from the latter to the child's month.

Produced.—In most cases a dose of castor oil and a proper regulation of the diet will be all that is needed; but in every case I would recommend the chlorate of petash, which is a specific; and a few grains administered three times a day will have a marvellous effect in curing the disorder. The month should be washed out after each meal, and a local application of the glycerin of borax be employed; or the affected part may be brushed over with a solution of nitrate of silver (gr. v ad (%)). Sir Whiliam Jenner recommends a solution of sulphite of soda (%) ad f%), from the destructive influence which the sulphurous acid has on the fungus.

Ulerrative Standitis (Ulerra-membranean absorbitis, Rilliet and Barthez) is a mild and frequent disorder, but in no way dangerous

^{*} Reynolds's System of Medicine, Art. Thrush, col. iii, p. S.

to life. It is more frequent in hospital than in private practice, It would seem to be an aggravated form of the membranous affection, which either advances to obseration, or in milder cases is absorbed without proceeding any further. The affected membrane in the first instance is white or dirty gray, or black, and the surrounding numbrane swellen and inflamed. The plastic expedation is thick, and is more or loss adherent to the tisens beneath, and, if raised, exposes a superficial bleeding alcer. Even when the explation is gently removed blood orges from the exposed surface. The affection is seen to occupy the inside of the clook, and to extend to the gums of the front teeth, which are swellen and spongy, bleeding on the slightest touch, and, by their retraction, ransing the teeth to become loose in their suckets. The check and lips in contact with the affected parts likewise because the seat of irregular olcoration, which may prove very obstinate, or degenerate into a more severe form. In mild and favorable cases, the ulcers being superficial rapidly diminish in size and heal quickly, the saliva becomes less in quantity, and the gums take on a healthy argenrance. But in some cases the alcers destroy the guns, and extend deeply, and are very intractable to treatment. They may involve the whole mucous membrane of the month, running together and extending to the hard palate; and when the disease in so general, the submaxillary glands are hard, swellen, and painful. The breath is offensive, and the salivary secretion is increased. The subjects of this complaint are deliente children, who have been badly fed and cared for. It is common between the ages of five and ten years, and it often prevails as an epidemic. The scrofulous children of the poor are frequent victims, particularly if their health has been further reduced by eruptive diseases or pneumonia, or if they possess had tooth. In one case under my cure there was an obstinate irregular ofcer on the gum, which had recoded from a carious tooth, and it resisted all remedies till the decayed stump was removed, when it took on healthy action. There is generally some febrile disturbance, which continues for a day or two.

In the case of a female child, nine months old, who was shown to me in May, 1877, by Dr. Wynn Williams, the electrical occupied the inside of the lower lip in three distinct patches, the largest being the size of a threepenny piece. The electration was not deep nor surrounded by inducation of the mucous membrane, which presented no variation from the tint of health. There sprang up from the base of the observed surface long whitish points, like the fungoid excressomes of an open wart. When that seen by Dr. Williams the affected part presented a peakise hard body, feeling like a wart. The child was suffering from brouchopneumonia, chiefly of the right lung, of one week's duration, and the lip became affected on the third day of the attack. The face was pullid, and the lips dusky and separated, the respiration was short and shallow, 60 per minute; the morning temperature 103°, the pulse 112; in the croning the temperature reached 104.2°, and the pulse 129. There was no observation in any other part of the month, nor any aphthons exudation.

When the examthematous fevers have altered the quality of the blood, or a young child is struck down by some acute disease with a high temperature, the morous membranes are prone to suffer, and especially the mouth.

Trentment.-This consists in attention to the general health; the diet should be regulated and the digestive functions attended to. In the shape of medicine the chlorate of potash is a specific here, as in other varieties of alcoration of the mouth in children. A grain three or four times a day in mater for a child a year old, and one additional grain for every year of the child's age up to ten grains will be a suitable dose. A drop or two of the fillness ladrochloric acid, and the addition of the fineture of cinchons, or the ammonio-citrate of Iron will soon bring about a cure in ordinary eases. Coldliver oil, quinine, and the syrup of the iodide of iron will be useful. If the alceration is obstitute, the application of a solution of nitrate of silver to the ulcer, or the hydrochloric soid is desirable. I have often known the gunsa to take on healthy action at once after an application of nitrate of silver (gr. v ad 5), and to be well in a week when chlorate of potash has been given at the same time. As in the sere throat of scarlating, brushing over the affected part with the tinoture of iron and glyceria is a good application.

Gaugierous Standillis (Concrons eris).—This is a serious and rares constitutional affection, attacking children whose blood is

^{* &}quot;I have only were more had the appartualty of wimoning it; but so futal, that is six one of these seven cases the patients died. The larger experience of other observers shows an equally unforceable result, since 20 out of 21 cases that came under the retice of MM. Billiet and Barther had a fixed termination, and a recent French.

deranged, and is a far more important disease than any of the varieties we have hitherto-considered. It may follow the eruptive fevers (particularly measles), typhoid force, and tuberculosis.

" In by far the majority of cases it succeeds to some scate illness, by which the health of the child has been greatly undermined. The disease of all others which some most to prodispose to this affect tion is measles. Of ninety-right cases collected by M. Tonnles, in forty-one, or nearly half the cases, it followed measles. In nice, it followed intermittent fever; in nine, typhoid; in seven, it is put down as due to enloued; in six, it followed pertussis; in five, sendet fever; in five, enteritis; and the remaining followed various diseases. Again, of forty-six cases collected by MM. Bouler and Califault, in thirty-eight it followed attacks of measles." Most authorities agree that the disease is most often seen between two and five years, but it may occur to any children up to twelve er thirteen. Lake the former disease, it is more frequent in hospital than in private practice. The disease is regarded by most observers as beginning in the mucous membrane of the mouth, with the formation of thick yellow patches of membrane, which terminate in alteration. A hard swelling also forms, surrounded by a tense intiltration of the cells ar tiseae of the check. The symptoms begin with fetor of the breath, and a discharge of saliva; the incide of the cheek is tense, bard, red, and shining, and it is usually limited to one side. In the centre is a bright-red spot, and the mouth is spened with difficulty. An irregular excavated uleer forms, which is covered with an ashy loose slough. The teeth become loose, and occasionally drop out, whilst the alreoli are laid bare, and sometimes become ascrosol. As the disease ndvances, the swelling of the cheek increases, and the central spot becomes a gangrenous exchar or slough, and blackened shreds of tissue are east off. The disease is usually limited to one side of the month.

Treatment.—The only reliable means of sure consists in the application of strong hydrochlorse acid, or nitric acid, and it is obvious that if such a remedy is to be of service, it must be active

writer | Dursley, Dr. Norm, etc., its, These de Strasbourg, 1849; who like reflected from different sources 288 mees, which did not all come in children, stans that 170 of the number, or 75 per cent., terminated family, "— Works Dismos of Infrary and Calif-Lord, 6th relation, p. 632.

and applied thoroughly whilst the patient is under the influence of chloroform. It may be necessary to repeat the application from time to time, and the mouth must be washed frequently with Condy's fluid, or a weak solution of obloride of solu. If the check is tender on the outside, a poulties or forumtation will be advisable. Castor oil, chlorate of potash, iron, etc., will be needed (Form, 9, 10).

Mercarial Selimnias. - Mercury, when injudiciously administered, may produce obseration of the game, loss of toeth, fetor of the breath, and salivation, leading to the various forms of stomatitis and gangrous of the mouth; but such cases are very rare, and we look for the influence of the drug in the greenish stools of infants, rather than in the excessive action of the salivary glands." In addition to those symptoms there may be swelling of the submaxillary glands and superficial olcoration upon the gusus, which may extend to the cheeks and tongue, giving rise to an ulcorous or gangrenous form of stomatitis. The constitution sympathices in the irritative febrile disturbance, and weeks may clapse before the affected parts resume a healthy state. Children so affected from flesh and strength, and are prevish and irritable. They are disinclined to take nourishment if the mosth is sore and painful, and that which is swallowed is imporfactly assimilated from the quantity of altered saliva which finds its way into the stomach. Nearly 30,000 children of all ages have come under my care during my connection with the Children's Infirmary and the Children's Hospital, and I have administered mercury to any of them who seemed to require it, but hardly ever saw salivation follow its employment before the completion of the first destition; and never observed that medicine, at any age, produced any affection of the mouth sufficiently serious to cause me a moment's anxiety." When given in a single or moderate dose it would appear to be ofminated by all the secretions, and not a trace can be detected in any organs or tissues. When, however, it is continued recklessly or intentionally for days together, the power of climination gradu-

⁺ West's Discours of Enfancy and Childhood, itle edition, p. 539.

ally fails, and it accumulates in the body, lessening the amount of fibrin in the blood, and increasing the activity of all the glandelar organs. "The chief channel of escape accurs to be the kidneys, but it is very certain that, at best in some cases, the drug is freely exercted by the salivary glands as well as by the intentions."

Chlorate of poinsh and sulphate of magnesia are both useful remedies, the former acting upon the mucous numbrane of the mouth, and the latter stimulating the action of the bowels. For the soreness of the mouth, a solution of nitrate of silver (gr. v ad (5j) should be applied twice a day, and every time after taking food, which should consist chiefly of milk; the parts affected should be gently wiped with a piece of soft rag dipped in the lotion of borax before mentioned. The employment of solution may be required to allay pain and presents sleep.

Gingirilis-Inflormation of the Gunn-Disorders Acasapanging Dantities .- Dentition in most healthy children is attended with redness, heat, and swelling of the gums, which are also tender, and there is dryness of the mouth in some cases, but often a free for of saliva. There is pain in suckling, when the child attempts to group the nipple, which it speedily releases, and cries, and is freful. When children are strong and full of flesh there is considerable disturbance of the system, and the cutting of each tooth is attended with heat and flushing of the face, sleeplessness, and fever. Cerebral disturbance, and even inflammation or convulsions, are occasionally observed; skin diseases and eruption about the scalp are common. In rickety children deutition is rotantel, and there is no derangement worthy of notice. Some children pass through dontition with little, if any, constitutional disturbance, our tooth after another appearing in regular succession, without pain or irritation of any kind. But it is not so in every case: there are many instances in which dentition is painful, and every new tooth either provokes a short attack of inflammatery forer, diarrhosa, salivation, or even a convulsion. The gums are tel, hot, and swotten, and the child is perpetually putting the fingers in the mouth, and is unable to suck and grasp the nipple; aphthess ulceration takes place, the child is feverish, cannot sleep, and is extremely restless and fretful; sometimes laryngismus or infanmation of the air-passages (bronchitis or poeumonia) springs up.

^{*} Treatise on Therapeutics, by H. C. Wood, M.D., 1876, p. 368.

or entancens cruptions, as lichen or strophulus. In some children the fretfulness and disturbed sleep are very trying to the parents, and not without anxiety to the medical attendant; the child grows pale and fractions, though the gums have been lanced and the feeth are appearing. It sleeps for a short time, then wakes up flushed and excited, and cannot rest again. The child is unestay, and puts the fingers to the menth, cries at any sudden noise, and will not leave the nume's arms. The servous excitability is great, and unless the child gets rest, it grows pullid and exhausted, refusing food, and often vomiting the little that is taken, the hands and hend are hot, the pulse is quick, and the temperature diseated.

Treatment.-In collinary cases a simple aperient, and rubbing the guns to and fro with a piece of white sugar will suffice; but if the gum is tense and poinful, and the tooth distends it, a free incision will give immediate relief. The lancet should be made to incire the gum in the direction of the alviolar process, although a marked and shorter transverse incision is sometimes advisable. If the child is strong, a grain of calomel, and a saline mixture (Form. 8 will be necessary to open the howels and remove any intestinal disturbance. If in spite of the gums being freely incised, and the mouth assist, the nervous irritation and sleeplessness continue, and the nurse and attendants are worn out with the restlessness of the child, sleep must be procured, and the nervous irritation alloyed. For this purpose, a mixture of brounds of potassium and hedrate of chloral is advisable at beltime, and it should be repeated if tranquil sleep does not ensue, while the bromide may be given during the day.

Transmitte—Cyannole Tanaillarie—Quincy—Conses—Symptones— Transment.*—This discuse sets in with rigors and febrile symptoms, pain in the head, limbs, and back, to which sourced heat and dryness in the throat. Any attempt at swallowing is extremely painful, and the patient feels as though there was a lump in the throat. The voice is thick and guttural, and the tongue is covered with a creamy fur. The pharynx presents a deep reddish tint, and one tonsil is noticed to be more swellow than the other, the discuss being usually limited to one side; a patch of lymph is seen conting the affected tonsil, and the set of swallowing causes

^{*} The diagrams from the threat affection of diphtheria and scatterious is considered in their respective chapters.

a darting pain through the sar on the affected side, and throbbing; there is a free discharge of saliva, and liquids return through the nose. The neck below the ramps of the jaw is tender and avoiden in some cases, and as the complaint progresses the inflammatory ferrer increases, till the stage of suppuration is reached, which or dimerily happens in five or six days. The disease may end in resolution, the inflammation and infiltration of the affected tissues gradually saleiding, or it may go on to suppuration, leaving a deep, ragged, excavated along, or it may terminate in chronic inflammation and enlargement. When suppuration takes place there is fluctuation, but the tonsil may be infiltrated with blood and secure, and the palate be much evollen without the formation of any pus.

Delicate children are occasionally liable to the complaint from rold and exposure to draughts of air when the body is heated, as

when coming out of a bot and close room "

Treatment.—If there is much tenderness below the jaws, and the little patient feels pain in separating them, two or three leveles will be useful, and a positive applied afterwards. At an early period, before any matter has formed, a few punctures with a bistoury guarded with a piece of list will reflere the tension, and drain the infiltrated tissues; the mouth must be continually washed out with warm water. At an surly period, if there is much februle excitement, a dispheretic containing autimony (Form, 7) or aconite should be given.

In some inflammatory affections of the threat in children, as in tonsilitis and general pharyngitis, half a minim of the finature of acouste may be given to a child in a tenspoonful of water every hour, or even half hour, with great advantage. But its effects must be watched lost it should depress the circulation too much, or reader the pulse unsteady. The remedy will generally convert the dry and hot skin into a sweating one, and control the formie excitement and restlessness; the pulse loses its hardness, and falls in frequency, the temperature is reduced, and relief follows in a short time. The tensils become less swellen and congested, and

[&]quot;Of 2000 cases of tornillitis transed by Dr. Morell Markennie at the Bospini in Discount of the Throng there were only 26 cases from 10 to 15 years of up; and 184 from 15 to 20. The most common period is between 28 and 20; after 25 there is a remarkable full. Young children are very little subject to the discount and before the age of the it is solden seen (Discount of the Thront and Now, 1880, p. 45).

the murous membrane of the throat more moist and natural. "If cought at the commencement, a quincy or sore throat rarely falls to success in twenty-four to forty-eight hours." Guaissum is another remedy which has long capoyed a great repute in the treatment of this affection. Dr. Movell Mackenzie thinks it far superior to account. It may be given in the form of powder, four or five grains in a little jam, every six hours, or the Truckisci Guaisei of the Throat Hospital Pharmacopoin may be prefered.

A grain or two of valoused to stir up the functions of the liver will about the headache. The patient must be fed with milk and soda-water, ten, lowerende, and thin water arrowroot, the tartrate of potash drink to keep the howels free, and beef ten to support the strength. Tousillitis is soon succeeded by prostration, and quintee and other tonics may be called for at an early stage of the affection.

Hypertraphy of the tousits may follow neate tourillitis, but more commonly it is seen in delicate children who are anomic, rickety, or strumons, or afflicted with a syphilitic taint. The disease begins as a chronic affection during the first two or three years of life.! The tensils project in the middle line of the fauces, narrowing the aperture, and interfering with swallowing and speaking. Children so affected sleep benvily at night, with the mouth open, and are restless. They are liable to cutarriol attacks and deafness. If they are young, and the tensils do not meet, local treatment by intrate of silver and perchloride of iron may keep the disease in check. As the age advances, and the general health improves, the enlargement under treatment subsides, but in too nuny cases excision of a portion of the cularged glands must be resorted to. Cup-ahaped depressions in the lower part of the chest-wall are frequently observed in children suffering from enlarged toneils, when they nearly meet, and narrow the entrance for the admission of air to the lungs. These depressions, due to imperfect expansion of the lungs, disappear after excision of the totalls, by permitting a freer entrance of air to the imperfectly

² Of \$100 cases. Dr. Morell Markennie met with 265 under the age at 18 years, and of these 54 occurred from 1 to 5, and 101 from 5 to 10 (sp. cit., p. 51).

expanded vesicles.4 The well-known pageon-breast sometimes arises from chronic calargement of the tousils.

Staple phoryegitis, or inflammatory sore threat, is an affection of the toosils, soft palate, and pharynx, unaccompanied by afternation or exudation, and is common among children during cold and changeable weather. It is either a simple idiopathic affection, or it occurs as the accompanionant of measles, scarlet favor, broughtis, pneumonia, croup, and laryngitis. It is much offener a secondary than a primary disease. The nuccous membrane of the parts just alluded to is swollen and slightly red, and a nuccous or sero-paralent secretion is seen upon them, particularly the back of the pharynx, which has a red, roughened, and granular appearance. The amongs membrane in the secondary affection is often dusky and purple, and the toosils are more swollen than when the one phaint is idiopathic, and arises from cold and exposure, or from avallowing builing liquids.

Symptonic.—The complaint begins with disturbed sleep and residesoness; there is foldile excitoment, as heat of skin, flushed face, bendacke, thirst, tenderous over the planyax, and difficulty in swallowing. The appetite is gene, and the child refuses to take food. The pulse and respiration may be increased in frequency, and the temperature reach 190° or more. In very young children there is often croupy rough and bronchial irritation. In one case under my care the tracked irritation was certainly secondary to the planyageal affection, and it travelled down into the brought and produced sufficative bronchitis and death. The disease is not dangerous in itself, but from the complications to which it may give rise.

The treatment consists in applying a piece of linen mg [twice fooled] dipped in tepid water to the throat under a piece of eiled sitk. If this does not give comfort, and there should be swelling and irritation of the cervical glands, a warm lineced poulties is the best application. In young children I have occasionally negped out the pharynx twice a day with a solution of nitrate of silver (gr. v ad (5)), and seen great advantage follow it when the disease has not invaded the trackers. In recent and neute cases, the temperature of the apartment should be warm, and the atmosphere moist. Milk and water, weak ten, and more laginous drinks should

Two Observations on Children, by Naugain Moore, M.D., St. Barthalouse's Repital Reports, 1874, vol. 2, p. 130.

be given as a diet. A refrigerant and saline aperient is neally needed (Form. 8), and disphereties and mild schalives of various kinds are useful (Forms. 7, 12, 76) to calm excitement, subdue insttation, and determine to the skin.

Retropharyageal abases consists in the formation of matter between the vertebral column and the posterior wall of the pluryux; it is most frequent in infancy and early life. Children of a strumous or tubercular constitution are most liable to the complaint, and caries of the exercical vertebre, or inflammation of the submucous arcolar tissue may provoke the disease.

"The cause is mentioned in twenty cases of the primary form, collated by Dr. Allin, as follows: Exposure to cold, ten cases; bulgment of hone in pharynx, eight cases; blow with a fencing feel, one case. In the last case, the button of a fencing feel passed through the right nostril into the pharynx." Sometimes no cause can be ascertained.

Many writers describe the disease as secondary when it follows the emptive fevers, as measles and scarlation, the inflammatory state of the pharynx involving the cellular tissue beneath, and leading to suppuration. It is then regarded as of biliopathic origin. "When thus occurring, it is similar, both as regards cause and enture, to lumbar aboses. In a few recorded cases the abscess has been a sequel to crystpelas." (Lowis Smith.) It has also been traced to inflammation of the lymphatic glands, between the pharynx and vertebras. (Fleming.)

Symptons.—The discusse generally sets in with fever and restlessness, furred tengue, heat of month, difficulty in deglection, and the impossibility of assuming a recumbent posture. There is also in some cases a stiffness of the neck, and pain in moving the head. As the complaint advances the respiration becomes labored, and field cannot be availoued without pain. Occasionally there is trough cough. The early symptoms in a strumous-looking child, two years of age, which came under the care of Dr. Oxloy, at the Liverpool Infirmacy for Children, were stiffness of the neck, labored breathing, and a croupy sound on inspiration, but the little patient was able to swallow and cry. Eleven days afterwards a firm elastic swelling nearly filled up the threat. This was punc-

^{*} Discount of Children, by Lewis Smith, M.D., 1989, p. 119.

tured with a histoury, and a large quantity of pus evacuated. The

The abscess can generally be detected on obtaining a view of the phary ax and fances, when it is seen to push forward the posterior wall of the phary ax against the relum pulati, or, if lower down, obstructing the lary ax and involving the respiration. The postnay even parend downwards into the pleural cavity, and excite dangerous mischief within the walls of the thorax.

When dyspassa threatens there is danger of suffication, and coughing or swallowing increases the paroxysus; the head is thrown back and the patient sits upright, with the tongue protruding from the mouth; the pulse is frequent and small, the aspect is livid, and death occurs from apnexs. In some rare instances the abscess has barst and deluged the tracker and bronchi, causing death by suffication.

In the case of a child three years of age, recorded by Dr. C. Elliot, of the Bristol Children's Hospital, slowly increasing dysphagia was the leading feature, followed by convulsions and death. Nothing could be detected on examination but some reduces of the faures and slight enlargement of the tonsils. There was no dysposen. Beef ten and brandy were introduced into the stomach through a gum elastic eatheter. After death "an abscess containing about two oursess of pus was found situated in the upper and posterior wall of the pharynx." There was no discuss of the ione, and the larynx and tonsils were healthy.†

Diagrams.—The disease may be mistaken for crosp, but the premiur stugh of the latter about distinguish it, and the indisous manner in which retroplaryngeal abscess creeps on; it is much slower in its development, and the respiration is not involved till a late period. The complaint is quicker in its progress when it follows the exanthemata than when it arises from disease of the mine.

Treatment.—When the abscess is detected it should be spoud, with a historry, in the median line, without delay, and the fager will sometimes detect fluctuation when an inspection of the fluces fails to discover anything wrong. For a day or two after the puncture the tumor should be occasionally pressed with the finger to squeeze out any accumulation of matter, and if the case goes

Brit. Mrd. Journal, 3874, vol. ii, p. 371.

¹ Th, 187% vol. i, p. 663.

on well recovery will take place in two or three weeks. If the abscess is detected early and opened the majority of the cases will recover, but if due to disease of the spinal column they are generally fatal. After practure, end-liver oil, the syrup of loddle of iron, quinine, nourishing diet, and pure air will complete the cure.

Commission production product or manger in a contagious and ecomon disease in children, often occurring as an epidemic in achools, or other places where a large number of young persons. are living under the same roof. Spoudle cases are occasionally met with, and boys are far more frequently attacked than girls. The discusse consists in inflammation of one or both parotid glands, sometimes, however, attacking one side of the face only, and terminuting in resolution; the justicles of boys, and the breasts and ovaries of girls, occasionally sympathize in the swelling, especially when the affection logins to decline. Ordinary mumps is usually excited by exposure to crid, and runs its conrac in four or five days. When one member of a family suffers the others also become affected, though some authorities (with whom I cannot agree) assert that the complaint is not infectious. When the blood is contaminated by typhus, and some other fevers, inflammation of the paredid may terminate in supporation.

According to Virchow the disease commences in the gland ducts rather than in the interstitial tissue of the parotid. When it arises from simple catarrh, the tendency to supportation is much less than when it originates in catarrhal inflammation of the gland ducts.

The symptons are folcile disturbance and headache; there is stiffness and pain in opening the jaws, and areding takes place heaven the check and the ear, extending down the neck along the ranges of the jaw to the submaxillary gland. The face is sometimes flushed and the child is very reatless, and even wanders at night.

Treatment.—If there is much swelling two or three leeches may be necessary, and a positive applied afterwards, but warm fomontations and a piece of flannel carried under the chiu mently suffice to bring about a cure. A saline and cooling aperient is destrable to relieve the feverish symptoms and open the bowels. The diet abould be exclusively fluid, consisting of milk, thin arrowroot, but, etc. If the gland remains calarged after the scute symptoms have subsided it leads to no had consequences, and disappears in the course of time.

CHAPTER XIV.

INDIGESTION.

Sparse for the inspection of the Court of th

The functions of the digestive system in infancy differ in a remarkable degree from those of adult life when the organs concerned have reached a higher state of development. The calls for nourishment to must the changes that are perpetually going on in the child are frequent, and too much care and importance cannot be devoted to this early period, when the stomach is so constantly normalised in preparing the food that is introduced into it for absorption and soutrition.

Children may be compared to small little whose circulation and respiration are very rapid, while the machinery of life is in active motion; in fact they live fast. These tiny creatures are continually pecking up food to compensate for the incossant waste in their physical economy. But the balance between waste and repair is soon overcome in favor of the former, and small birds are short lived. In children, owing to the further development of the organs, the process of repair is in excess of waste and leads to growth.

Indegestion is most common in infancy, and decreases with growth and the completion of the first deutition, when the stomach in healthy children becomes capable of hearing a mixel diet. The digestive organs in early life will only assimilate the simplest diet, and any deviation from it will be followed by discomfort, and symptoms which make up the sum total of indigestion.

In the predental period of infancy the food reaches the atomach almost as soon as it is introduced in the month without mastimtion. When once it is in contact with the gastric mucous membrane, a secretion is poured out; and the two combining form a substance called chyme, and the process is termed chanification. The next step consists in the action of the muscular cout of the stomach walls, forcing the fluid mass through the pyloric orifice into the duodenum, where mixing and becoming incorporated with the billary and pancrentic socrations it is transformed into a oreamlike substance termed chyle, and this process is called chylifortien. The villi which are scuttered over the surface of the small intestine absorb the nutritive elements, and convey them into the lacteals, and so into the circulation through the receptaculum ckyli. Those portions of the food which are useless, or resist absorption, are conveyed along the remaining tract of intestime and finally thrown out of the body as excommunitious matter, and this process is tormed defection. In a state of health these processes are carried on without our consciousness, and a sense of comfort and satisfaction only is felt. Where digostion is imperfeetly performed, either from defective health, or from the quality of the food that has been taken, then indigestion results, and the symptoms that ensue are oppression, pain, weight, and distension. The food is either rejected by vomiting, delayed in the stomach, or passed on into the bowels, ransing diarrhosa, or some other form of irritation in these viscorn.

We have here to consider what happens in infants and very young children in these cases. There is deranged action in the stomach itself, an alteration in the character of the secretion, and irregular or unhealthy nuscular action. But indigestion once established does not limit the resulting disturbance to the stomach itself; it involves by sympathy other and distant organs, and there is not an important viscus in the whole body that does not share in the general derangement, so much so, that it frequently distracts our attention from the stomach, and deludes us into looking at the sympathetic disturbance as the primary evil.

In children, as in adults, the stomach may have lost its vigor and tone, and therefore be incompetent to fulfil its functions; but in the tast number of instances indigestion originates from the quality and quantity of food that is introduced into it. The macous membrane is readily irritated, and resists the offence, just as any other organ of the body becomes irritated by some abnormal stimulation, and finally fails under the excitement, even though there may be no discoverable alteration or gross structural classics.

Hence, then, it is proverhial in early life that the stomach being delicate and susceptible to any disturbance, we should be most exceful to select a proper diet, to consider the quality of food that is supplied, to measure the capabilities of the digestive system, and to deal with them accordingly.

We have no need to pursue more than cursorily the question of mastication, because it is the digestion of lafancy we are now mainly concerned with, and yet it is necessary to allude to the development of the leafh. There are two sets of teeth, the decidence and the permonent. In infancy there is a period of several months before any teeth are developed, and when therefore the function of section is not required. In the early months of life there is no secretion of saliva. (Pary). The mother provides the necessities of living in the form of milk, which her child consumes till growth and development fit it for an independent existence. By the time when the mother should wean her child at seven or eight months, the teeth begin to appear, and by the and of the first year in healthy children there are usually as many as twelve. There is no longer need for a fluid diet excinsively, but among the lower classes, prolonged factation to diminish the risk of repeated pregnancies, is carried far beyond the limits of health in the mother or her offspring. Children of lifteen or sixteen months old may often be seen olinging to the breast for their only materiance in the out-jurient department of our hospitals.

When the child is once permitted to sustain itself another difficulty is presented. In many instances it is either provided with food which is improper, or it devours it too hastily, and so the troubles of indigestion are established. Food imperfectly musticalled resists the solvent action of the gastrie juice, and irritation of the digestive organs arises.

Regarding the process of insolimation, the secretions of the paredid and submaxiliary glands are poured into the mouth, as well as that of the lingual and other smaller glands. Paredid saliva, is man at least, is watery, and acts as a solvent; submaxiliary saliva is more viscid, and contains more of the active principle, ptyslin, which converts starch into glucose or grape-sugar.

Digration of Starch.—Starch is a non-nitrogenous principle, entering largely into the composition of some foods. Whilst it

remains in this condition it resists absorption till the digestive system exerts its influence upon it. The first conversion is into dextrio, which much resembles starch, and then into sugar, which is easily absorbed. The action of the saliva converts starch into sugar when the possess of mustication is properly carried on. As the food passes out of the samuels, the secretion of the panerens and the glands lining the mucous membrans of the intestines exert their action upon the remaining starch, and further transformation into sugar takes place, and the bloodvessels convey the latter into the circulation, whilst the unchanged starch-grandles mix with the executions and are carried out of the system. Starch is not naturally a part of the food of very young infants when the digestive functions are imperfectly developed. Sugar is the form that suits them.

Digration of Segar. This is principally the cane augur which exists as a juice in many plants. It is so readily soluble that the digrative functions are in no degree taxed when it course the stomach, by which it is readily absorbed into the circulation, undergoing a change into graps sugar.

In some forms of dyspepsia, and especially in that of children, lactic, batyrie, and other acids may be present as secondary products, arising either by their respective formentations from articles of food, or from decomposition of their alkaline or other salts; and the tendency is immensely increased by succharine articles of diet.

The envelopes of the fat-cells are dissolved by the gastric juice, and their contents set free. These run into droplets, and are possed on into the small intestines, where they are acted upon by the bile, and the paperentic secretion. By the agency of these the greater part of the fat is smulaified, and therefore rendered capable of absorption; partly split up into fatty acids and glycerin, and partly suponified. The absorption of fat appears to be of a physical rather than of a chemical nature.

State of Digestion at the Time of Wesning.—In even healthy children this seldom takes place without causing some disturbance in the constitution, and the symptoms that arise are generally those that indicate disorder in the functions of digestion. The change of find when the mother ceases to suckle her child is fraught with risk for some time, the child is fretful and sleepless, has flatalence,

^{*} See Chap. II, p. 28; where this satject is more fully countered.

diarrhora, or voniting, and forthwish it declines, looks pinched and cureworn, has a weak cry, and the skin shrivels from the absorption of the subcutaneous fat, reduces about the arms and thighs is observed, and the changed aspect is remarkable. Not that this abnormal condition cases in all cases, for many braithy infinite bear the change without munifesting either local or constitutional disturbance.

Indignation is constantly associated with wasting in children; when they are so suffering, the food that is swallowed is at our rejected; they lose color and strongth, the muscles waste, and the limbs become attenuated. The child refuses the breast or takes it greedily; then begins to whine and ere, and can obtain so sage till the milk is rejected, because the digestive powers are smalle to assimilate it. In addition to these symptoms others arise, as heat about the mouth, with pair and acid eractations; the motions are often slimy, offensive, and of a dark-greenish hur, or they are pelbly, and there is constitution. When the child is fed on milk or has a wet-nurse the motions may be puls and almost like the milk that is swallowed, which passes through the bowels unchanged t or the motions are variable in character (diarrhosa altenrating with constitution), being loose and thin at one time, and sticky and clay-colored at another, with green spots like bits of spinordi among them;

Visiting, so frequently present in these cases, is a refer action of the servous system, and is a common symptom of indigestion, or irritability of the stemach in infancy and childhood. It is also symptomatic of disease of the brain, of the large, of the various exanthemata, and diarrhess depending on poisoned blood. It is a symptom that invariably excites alarm when it arises without any discoverable cause, and cannot be attributed to everfeeding or mechanical irritation. It usually happens that the milk does not agree, either from fatigue, indiscretion in dist, or had health in the name; what is swallowed soon causes flatulence and pain till it is finally rejected as a curd from the stomach, and the child at once seizes the breast again till the same symptoms recur, or after some discomfort it passes through the stomach and creates intestiral irritation and diarrhosa. The same is likely to easne when the milk is braitly, but the child has been allowed to go too long without food, or is fathered from heat or overexcitement. If, from any of these circumstances, veniting ensues, it is important to allow the stomach rest, and whilst its tone is lost, to give a teaspoonful of cold water or barley-water, till the sickness has passed off. When the symptoms do not yield to these measures, and the child is otherwise in good health, a mild mercurial and milk and lime-water given by a teaspoon will generally afford relief. It may at the same time be advisable to prescribe small does of hydrocyanic said in a solution of magnesia, and to apply a mustard poultice to the epigastrium.

During the continuance of this state of things the child is weakly, and an erythematous rash may appear on the bettocks, or ecrema on the face and scalp. I have seen this appear and disappear according to the severity of the indigestion, and in one case it was so but that the cyclids became adematous from the swell-

ing and the features distorted.

Associate is a common symptom in dyspepsia, and when it is present children will struggle to the numest rather than swallow one particle of food. Vitarted appetite is sometimes seen in children. In one case under my care, a girl suffering from answarea and allouningria, decoured the most loutherme things possible, and required careful watching to prevent her from so doing.

Beliach is seen among children suffering from worms in the intestinal canal or measureric disease. It is also very common in cases of chronic hydrocoplains, and is by no means rare during contalescence from measles and some other scate diseases."

Then there is a form of dyspepsia not uncommon, especially in boys † The tongue loses its epithetium and is superficially alearated. Children thus affected bolt their food and have ravenous appetites. They lose fiesh and do not thrive; they are pullid and delicate-looking, and if the condition is allowed to go on it may

pass into mesenteric disease.

In some cases dyspepsia and intestinal irritation are brought on by giving young children too much animal food, which they swallow without sufficiently masticating it. After a time, in addition to epignatric pain, tenesmus and bearing down come, the child wishing to go to the closet every minute; the motions are imapy, thick, and brown, with jullylike close of blood on them, and there are faintness and names before the bowds act. This form of indigention may, if the symptoms are not attended to, pass into dys-

^{*} See Chapter X.

entoric diarrhera, and the child may distof mesentoric disease and phthials.

Pyroa's is sometimes seen in children of eight or time years of

age, demanding the same line of treatment as in the adult.

The courses of indigestion in infants arise in nineteen cases out of twenty from defective power on the part of the stomuch to assimilate and digest the fool that is supplied, or to the food not being always of the most digestible quality. I remember a lady who had five children, and all of them reached the age of one year without any illness or drawback. All the five children were wetnursed. The sixth child was born at the full term, and in every respect was strong and vigorous. A healthy wet-nurse was procared whose milk presented microscopically no deviation from the healthy standard, she was twenty-five years old, and all her functions were regular. The child at the age of two mouths had m erethoustous oruption of the face and scalp, attended with great stehing and much redness. Small Vesicles and prominent elevated points soon appeared over the inflamed parts, and finally ran into one another, causing exceriation and superficial alteration of the surface. The tongue was clean and without aphthie, the surface of the body healthy, and there were sedden less than three or bur motions in the twenty-four hours, of a bright-yellow color. The child occasionally brought up a curdiike mass of milk, almost as seen as swallowed, and the incusiness erinced by a unining cry, and the incernant drawing up of the extremities, would often nomentarily coase, after lasting many hours, by the expulsion of wind from the stomach, or by the action of the lowels. This was cleany owing to indigestion, and imperfect assimilation of the milk taken; either it was too rich, or the stomach too feeble to exert the recosary changes, or the mucous membrane secreted an undue amount of acid, and caused fermentation in the food products. Barleywater, substituted for a time, would arrest sickness and spasns, and so would bringlass and water, and then the child would return again to the nurse's malk for a few days without any inconvenience. But after a time the same inconvenience would return, and then it was finally determined to discard the nurse, and try the effect of cows' milk with an equal quantity of water, and one tablespoon il of line water to the bottle. A third of a bottleful was allowed at each feeding at intervals of two hours. Immediately the change of diet was instituted, a remarkable improvement set in, the suption began to fade, and the child was brick and lively. But after a few more days had elapsed the same solicity pains and flatulence returned, the child was rule and pinched, and the motions became perid, offensive, white, and sticky." It was obvious that the liver was not pouring out its proper biliary secretion, and to meet this, a pewder containing a grain of gray powder, two grains of rhuburb, and half a grain of cinnamon powder, was given every night, whilst a carminative mixture of hiearbounts of potash, sal volstile, and dill-water was given at intervals during the day. About turnty drops of brandy were added to each bottle of milk. An improvement soon set in the motions assumed a more healthy character, and the child became bright, the features filled out, it sleps, and enjoyed the food, which now caused scarcely any flatulence or discomfort. A still further manifestation of improvement was shown in the decline of the eczematous eruption, cace so perescent and troublesome, but how fading with the child's better netrition, and only giving evidence of its latency by occasionally showing itself when the digestive functions were temporarily disturbed.

The alimentary cannot is extremely aensitive in early life, and a mother learns from experience that if she is careless in keeping her own digostion in proper order she is sure to derange that of her offspring. After the seventh or eighth month, when the teeth legin to appear, the child will need some solid article of food, and it is then that bisenits and some farinaceous articles of diet may be given with the milk, later on a little beef ten or gravy, but not meat, till the second year. The irritation caused by the coming molar teeth induces the child to make masticatory efforts, and this excites the action of the salivary grands.

The other causes of indigestion are an impure atmosphere and rentined rooms, especially if several children occupy the same apartment. Hot sultry weather will frequently induce the complaint, and children rearest in towns and cities are more frequent sufferers than those brought up in the country. Artificial feeling is probably the most frequent cause, especially that by the bottle, from the liability of the contents to turn sour and disorder the digestion. All children so suffering should be fed with a teaspoon.

Older children experience indignation from cating unwholesome

food, as sweets and raisins, observies, etc., which, undergoing only partial change, cause pain and intestinal irritation. They are often feverish and drowsy, have headache, and are disinclined to move; they bring up what is swallowed, and complain of pain over the epigastrians. Their nights are restless, and the nervous system is so upset that a convulsion may follow. The neglect or continuance of the disease may lead to aphthous alceration of the mouth, diarrhora, or erlampsia.

Treatment—In addition to the hints and augustions already thrown out in this chapter, concerning food and judicious feeding, there are other matters to be recollected. Three conditions appear to be necessary to ward off indigestion in an infant, and when they exist, it is remarkable how slight is the stomach demagement. These conditions are: I. The child to be healthy lown; 2. The mother to be healthy, if she supports her own child; I. The cow's milk used to be pure, from the same cow, and to be properly diluted.

The same in operation requires to be diligently sought for, and a careful inquiry should be undo into the circumstances of each individual case in order to remove it. It sometimes happens that an emetic will get rid of the offending material at once.

Care in nursing and proper feeding will often ours the disorder. The fixed alkalies of line and magnesia may be added to the nilk; If there is acidity, an occasional powder of soda and rhubarh is of service, and a grain or two of mercury and chalk may be added when the biliary secretion is deficient. It is a good plan to give alkalies when shore are free neids generated in the stomath; a grain or two of bicarbonate of potash with an volatile will prevent the congulation of the milk and the formation of a curl. Dandellon and calumba may be added if the stomach has lost its tone and the liver is inactive.*

Alkalise ought not to be continued for too long a period, and the electronistance that could be consisted by no means implies that there

is acid in the stomach, because the gastrio juice may be insufficient and the stomach weak. In that case the mineral acids are suitable to the youngest child, the hydrochloric or nitric acid, or both combined." If there is sickness and debility, with scanty secretion from the liver, hydrocyanic acid in combination with nitric acid may be given.† Bark and nux vomicu are also useful in some cases?

Indigestion in children sometimes assumes an exceedingly neuteform. From being comparatively well, a child becomes suddenly ill, restless, and feverish; its circulation and respiration are excited, and its temperature cans up to 105°, or even higher; the mother thinks the child has caught sold, or is commencing some feverish attack, but the suddenness and character of the seizure repter this rice unlikely. This suddenness is the great characteristic of sente indigestion, and at once points to the real cause, and relieves the anxiety. In such cases it is well to give an emeriof ipecacuanha, with a little antimonial powder and calomel. The child vomits, is at once somewhat better, and if its bowels are opened subsequently, in a few hours the alarming symptoms disappear. The quickness of the decline corresponds to the acutoness of the attack.

In chronic indigestion change of air is very serviceable, and one wet-nurse may have to be changed after another; calumba, bark, and sitric acid are useful in these cases. In older children,

the citrate of iron and quinine is a valuable remody if there is attention.

Dr. Lauder Branton advocates for children with defective digestion, stale bread out very thin, and the butter well rubbed into it, in preference to bread out thick, with a thick layer of butter, commonly seen in the nursery. In doing this the fat becomes finely subdivided, resembling the condition found in milk.

Diameter is produced by many conditions, and among children is more often a solutary than a discused process. It is of country occurrence when a septic poison is generated from the decomposition of vegetable matter, or the atmosphere is charged with missenatic effluxia. After absorption through the longs into the blood, the intestinal mineous membrane becomes irritated arthexcited, in virtue of an inherent disposition on the part of the economy to eliminate these noxious agents."

We need with it again, when water containing organic impurties, obtained from the vicinity of graveyards and stagmant posts, is used for drinking purposes. When contaminated with felial

^{*} See Lectures on the Infective Processes of Discape, by J. Serdon Sanderson, M.D., LL.D., F.E.S., December, 1877.

gases, fermentative dyspepsia arises, and the bowels show signs of a disorder, varying from simple irritation to cholemic jurging, gramps, and loss of body heat."

As a healthy process, a sharp attack of diarrhou proces its own cure, irritant and offensive matter being thus got rid of by the bowels, when the stomach cannot assimilate the food that is taken. We aid these efforts when nature fails to complete the cure by administering such remedies as remove any morbid materials from the system.

Discrime is summen amongh in infants when too much milk is swallowed, or when rich or star milk, instead of being thrown up by vomiting, passes on into the intestines, and creates britation there. Exposure while dressing, insufficient clothing, the use of too cold water in washing, and the neglect of cicanliness, will all induce excessive peristaltic action of the bowels.

Statistics clearly prove that there are few discusses in infancy and early life of greater frequency or danger than diarrhou; it will often set in from slight or unascertainable causes, and decide the fate of a young shild in a few hours. The delicary of the stometh and intestines in infancy renders this one of the commonent allments. If the supply of food is not of the simplest kind, and given in small quantities to said the tender age of the child, the process of digestion and absorption will be decauged, and the local disturbance thus initiated will convey the irritation to some other organ, and expose the life of the shild to considerable peril.

Diarrhea in children may be conveniently grouped into the forms enumerated at the commencement of this chapter. This is, however, at best, but an arbitrary division, for simple diarrhous may pass into any of the other varieties, if the irritation lasts long enough to excite aufficient disturbance in the mucous membrane; and it is often impossible to separate them in practice.

^{*} The dissination in the number of denths from technitic discribes thering the less mass years is unifuly attributable to impressed scattery legislation, and is for less despendent as temperature and other atmospheric confidence that is generally supposed. Indeed, the reason of the Regissure General for 1877 show that the recently of indicate from this cause was, during the third or Machadians quarter, not teach more than half the average of the series proceding surmain quarters. The power in receiving higher wages, are enabled to large in better bosses, and is similar a superior quality of fixed. This change in their social position will ment likely indices them to extend greater tigitions then forwardly, and will anywher them to the danger of any unhealthy inflament that may spring up around them.

1. Simple Diarrham (Catarrhal diarrhea) .- In this variety there is an excess of natural action, the evacuations are copions, related and frequent, and the child, if an infant, is soon exhausted in consequence. The attack may at first be painless, and as there is a loss of consistence in the motious they are equirted out with some modic effort. The evacuations are feeal, and if at first greenish, ther become reliew as the symptoms subside and improvement sets in." The early symptoms of simple diarrhau are hardly noticealos if the discharges are moderate, but there soon follow general discomfort and poevishness, the child is disturbed in its sleep, and, perhaps, becomes languid and puler than usual. The tongue may be slightly control, and there is usually some thirst and diminished appetite. When the attack is acute there is sickness, thirst, and dryness of the mouth; the strength is reduced, and in a for house the child may be much weakened. The little patient becours sunken about the eyes, the features are sharpened and even sellaysed, and the footabelles are depressed; there is sometimes fobrile disturbance with cough and broughisl irritation; the abdomes, may be swellen and tender from flat elence, or concave and empty If the diarrhost goes on actively for a slay or two, flesh and strength are rapidly but, the muscles feel soft and flabby, the pulse becomes quick and techle, and life is placed in imminent danger. The change in the character of the evacuations consists in their being thinner and more copious, though they seldom lose their feetlest appearance, except in very severe cases, or where the disease is obstinate. In these cases the motions soon become offensive after escape from the body, and may be even greenish and slimy.

When the diarrhers is sharp and continuous it sometimes in duces so much relaxation of the sphineter as to cause prolapers

ami.

The anotanical changes in the lining membrane of the intestinal tract consist in congestion of the vessels, which disappears after death. There would seem to be no pathological changes in the simple form of the complaint, even if it proceed to a fatal termination.

³ The normal form of the infantile faces in the first year is pappy; the color is yellowish. Bloc that of the walk of egg! the small is builty avail, mover patrid, and only in children who are fed apon a most dist repulsively pumpent, so in the shift; is have years they are no longer to be distinguished from the situht. — Foyel, Discuss of Children, 1874, p. 123.

2. Billion distrikes may be witnessed in some children who est inordinately of animal food, and live too well for the wants of the system. Impure milk, like impure mater, is capable of giving rise to this form of diarrhou, and in sovere-cases the symptoms may become dysenteric." A large quantity of bile is secreted by the liver and poured out into the intestines, which it irritates. The disease is most common in hot wenther, and of course for more frequent in tropical climates, when the liver is apt to be congested from diminished respiratory action. It arises from an excessive secretion of bile, which stimulates the borrels to frequent action, the motions being copious, lease, and of a dark-yellow or green color; the urine is scanty and high-colored, and may contain traces of bile also. The secretion of bile may be enough to provoke fever, unless it finds its way freely out of the system.

3. Chilerate diarekee (cholera infantum - gastro-intestinal entarrh-Rilliet and Barthez) is most common in infants, and in these who are early weamed or hadly fed. The disease usually follows a rapid and fatal course. Its frequency is much greater in cities than in country districts, and in summer and autumn, than at other seasons of the year. "It is so frequent during the period of first dentition, that some writers consider dentition a cause," (Lewis Smith.) It is in my experience far more frequently due to atmospheric influences and errors of diet. It usually commences with simple or inflammatory diarrhou, the child loses its appetite and is fretful, then it is seized with purging, and occasionally with vomiting, attended with prestration, pallor, and symptoms of sinking. Violent retching sometimes ownist with choleraic diarrhoss, and the disease may set in very suddenly, and rapidly proceed to a fital termination. The tongue is slightly coated or clean, smooth, and dry, and the pulse quick and small. As the disease progresses the respiration becomes oppressed, the urinary secretion is suspended, and the surface of the body is cold, damp, and sometimes livid. The discharges at first are thin and focal, or frothy, with mneus or altered bile; but

[&]quot;An epidemic of diarrhous traceable to one special milk supply, is described by De. Philips as having occurred at Upper Norwood in September, 1977. The armok was subsered in with rigors, point in the limits and pyrexis. The bowel discharges were "of an offensive billions character, going on to manus, and in some instances, bloody stoods, with fermionis." There was no dutal case, and the disease yielded to matematic in a few days.— Medical Economy, Jan. 19th, 1875, p. 29.

in the course of a few hours there are no traces of a billary serstion whatever, the evacuations being copious, frequent, and fixe rice-water or natureal grach, from containing shreds of intestical opithalium. It is the excessive discharges of colorless fluid which distinguish this form of diarrhom from any other. So great is the quantity that one evacuation will saturate the napkins of the shibl, and completely sonk through the bed linen, as though they had been kept under water for hours. When the stools are pale and finid there is no odor belonging to them; but if they are in any degree feedlent, and yellowish or greenish, then they are extremely fetial and offensive, and, notwithstanding the utmost cleanliness, the eder is at once perceptible on entering the sickapartment.

At first there are evidences of pain and griping sensations in the stouach and bowels; the bands and extremities are cold, the face pinched, and the eyes hollow. These is usually a craving thirst, and fluids are no sooner swallowed than they are brought up again; all appetite is gone, and sleep is broken and weefreshing. If the discuss does not soon yield to remedies, the child passes into a state of come and dies. If the discuser lapses into a chronic form, the evacuations may assume a dark-greenish and putrif character; the belly becomes tumid or tympanitic, and the tengus is covered with aphthes. The discuss may and fatally in a few hours or extend over some weeks. Cases apparently hopeless sometimes recover.

The fiver has been observed to be enlarged in this affection by several writers, but the most constant anatomical change would appear to be colorgement or softening of Peyer's patches, with an erythematous or inflammatory condition of the lining maceus membrane.

The following is an example illustrating these several points: A female infant, ten months old, was seen by me on July 10th, 1868, at 8 a.m., having slept only two hours during the night, and not at all the day before. It had been taken out in the air, and the want of sleep attributed to being beft in the sun. The bowds seted three times before 3 o'clock on the preceding day, and again at 3 a.m. next morning; the last motion was very outery, but feeal. On my visit the child was cold, pinched, and collapsed, eyes languid and set, lips very blue. The child was at once placed in a warm bath, and twenty drops of brandy given in some arrow-

root, which she greefily sucked. The circulation almost at once returned in the skin and lips, and she was then taken out and put into a blanket; but gradually the arterial bue deserted the lips, the surface of the hody was pale and contracted, and she became fival as before. She was again placed in the bath, and precisely similar symptoms resulted, the color returning, and the child assaming a brighter aspect. When removed from the fath she as quickly as before became blue and collapsed, but to a somewhat less extent. A mixture of aromatic spirit of ammonia and apirit of chloreform was given, and a mustard positive applied along the spine. At 11 a.m. the child had rallied, and there had been a colteless watery motion without a tinge of bile. The medicine and beef ten were given alternately every hour. At 1 v.m. dilute sulphuric acid with spirit of oldoroform, was prescribed every second hour, and at 5 r.m. the child had rallied, though there had been three similar rice-colored watery motions, after which more decided rollapse set in, and the child expired with a slight convulsive solzure et 7.45 P.M. No post-mortem was allowed.

4. Congestive Informatory or Morous Distribus—Entero-cities—Meas-enteritis.—In this variety there is a considerable degree of inflammatory action, quickness of pulse, and constitutional disturbance. The evacuations contain a large quantity of thin muons, which afterwards becomes thicker and approaches the color of pus. The motions are neither frequent nor excessive; they are usually variable in color, sometimes being greenish and offensive like chopped spinnels, and at other times yellow and mixed with numers.* Straining in going to stool is a common and distressing symptom, and more or less blood is intimately mixed with the naccus or feeal unitter.

Among the causes of this form of diarrhou may be enumerated damp and cold, and transitions of weather, but errors in diet would appear to be a fortile source of its origin. If the nurse's milk is too rich, or in any way unhealthy, it is very likely to set up diarthou in any form. It may be a sequel to choleraic diarrhou, the

^{* &}quot;Dr. Grassa segands this green matter as a secretical from the execute menderate of the small intestines, and not bile. Drs. States and Golding Real (Medical Grantin, Sept., 1843) mention in cortage to blood which has undergone a observed change."—Quested from Charcalall's Zhietsen of Children, 1848, p. 523. Halland hald that it was the execute of the gustro-intestinal coral scient open by the gustria judge, and indirecting immificient or impurper food. It is obver the sign that scenning should be instirated, the member's milk too longer being a sufficient field.

bowels remaining irritable, and producing chronic inflammatory changes in the nurcous membrane, so leading to gradual death by exhaustion. I quite agree with Meigs and Pepper, who consider that whether discribes is caused by improper food, summer heat, dentition, or epidemic inflamesa, the complaint, if it becomes chronic, is apt to terminate in this disease. It is not unfrequently met with in children in the outdoor department of our hospitals, and I have long been of the opinion that the complaint is traomife in them to exposure to heat or cold. The cases we ordinarily meet with during the summer are of this character, and hence its frequency among the children of the poor, who are at the same time hadly fed and reared in an unhealthy atmosphere.

The cutting of the teeth may exert an influence in causing distribute, as it does in setting up irritation in the brain and other organs. It is common between the ages of six months and two years, when the first dentition is completed.

The disease may be neute or chronic. In the first form the symptoms are active from the first, inflammatory products passing off from the intestines, and the disease acidom lasting more than a week or ton days. The chronic forms of the disorder may continue for weeks or months; there is a gradual loss of flesh and strength, and the bowels are perpetually acting.

The morbid appearances are a thickening or inflammation of the intestinal mucous membrane, which becomes red or of a darkishgray bue, with the evidence of ulcoastion or enlargement of the glandular follicles lining the colon and small intestine.

Muco-enteritis may follow an attack of menales, pneumonla, whooping-cough, or typhoid fever. It is prone to attack feells and delicate children of strumous constitution. The abuse of aperient medicines may induce a simple diarrhox which passes into this form, and wearing, or the change of a nurse is another cause. The morbid anatomy of the affection shows disease of both the large and small intestines. In the large intestine, the sigmoid flexure and descending colon are chiefly affected; in the small intestine the lower part of the ileum. In the neuto stage,

^{*} Houses of Children, 5th edition, 1974, p. 384.

^{† &}quot;The present prevalence of distribut coincides enactly with that time while the process of destition is going on most actively, and that exactly half of all most of distribute construct is children between the upon of air mostles and two years."—Walk, on the Discourt of Informy and Children, 1850, p. 667.

the mucous membrane of the intestine is increased in vascularity and softened.

Thermic diarrhou is the form met with in summer and especially in hot climates. It has been well described by Dr. C. G. Conegys and Dr. H. C. Wood. It may be designated "thermic or heat diarrhou." "Any one who has seen," says Dr. Wood, "as I have this summer, the child on whom drugs had ceased to act, and who was seeningly dooned to die, releved in twelve hours by enforced cold bathing, every three or four learn, will grant to Dr. Comegys the credit of having introduced one of the most life-saving improvements in modern infantile thempenties. The sudden surest sleep, replacing, after the bath, the fretful nights and days of norest, is a thing never to be forgoism when once seen, and the arrest of diarrhous is certainly no less remarkable."

"We are summoned, in short, very often to see a child with a hot skin (temperature 1023°-105°), rapid palso (130-150) and breathing (30-40), with frequent purging of somiffuid, greenish, watery, fecal, and half-digested matters; the mouth and tongue are day, the thirst is intonse, but the water given to appeare it is quickly thrown off, the eyes are staring, pupils contracted, insomnia, relling the head, and attering distressing cries, due to the headache from hypersenia of the cerebral vessels and the unappeased thirst." The bath is first at the summer temperature of 75°, the feet and legs are first gradually immersed, and then outer is poured over the obest and abdonue till the whole body is under water. Colder water (85") is then poured in a continuous stream over the upper part of the head, and this is kept up for lifteen minutes. When the child is removed from the bath it is wrapped in a woollen showl, and placed in bed with additional covering. It falls usleep, the skin is cool, the pulse and respiration fall in frequency, and the temperature is at or below the normal standard. If the symptoms return the Eath may be resumed three or four times a slay. The internal treatment consists in giving beef tea, milk, and lime-water; "one grain of quinine and a half to a teaspoonful of whiskey every three hours for a child eight to sixteen months look formidable, but they will be borne admirably."

^{*} Sonstroke or Thereic Feyer, by Dr. H. () Wood, Philadelphia McGod Times, August 5th, 1876, p. 542.

With the departure of the fover, bismuth and pepsin are given to restrain diarrhors and assist digrestion."

5. Lieuteris Darrobox.-This form of diarrhea, knows as lientery, is characterized by the passage of undigested food through the bowels; it is very commonly seen in artificially reared children, especially among those who are subject to mesenteris disease. Food which they cannot assimilate passes through them. Mest, or bad milk, or vegetables, on which the gastric juice has no action, pass through the stounch, setting up initation in the lowels. The food undergoes scarcely any change in its justage through the long and tortuous length of the alimentarr canal. Shortly after eating the child experiences discomfeet, and passes the meat, which has just been previously taken, without the secretion of the steamch having exerted a solvent action upon it. It is probable that the stomach is feel to and primarily at fault in so rapidly disbulging its contents. The child's appetite is gready and never satisfied; there is great debility and loss of flesh, because the food is not absorbed, and there is thirst and

Dynamic Director.—When the discharge of muons from the bowels is excessive, and is attended with a considerable quantity of blood also, and there is no fover, we may recognize this form. It is not exactly one of acute or chronic dysentery, but of great congestion of the intestinal vestels, leading to their rupture. There are feculent discharges, with tenesmus, pain in the body, and wasting, and the child loss flesh rapidly. Dysentery may be described as a severe form of muco-enteritis, with more pain than

is felt in dinrebora.

general irritability.

Chronic Diarrobea.—This form may be, and often is, the consequence of the scute forms passing into it by slow degrees, or it may follow cold and overfieding, the use of sour milk, or the milk of a wet-nurse which is in all respects apparently builtly. The continued discharges from the bowels gradually reduce the strength and impair the powers of nutrition. A chronic state of irritation or cutarrh is induced, and the longer it hats the more difficult will it be to control. In this form of the disease the motions are variable, sometimes being copious and at other times quite

^{*} Cool Bathing to the Treatment of Inflavoratory Borel Allections through Sources, by C. G. Comegye, M.D., Philadelphia Medical Times, July 1745, 1875, P. 665.

thin and slimy, with golatinous masses of muous streaked with blood. As we have seen in the disease known as "liestery," any andigested food in the motions is significant of faeble digestive power and impaired nutrition; the milk or other articles of dist pass through the stemach rapidly, and in many cases there is a deficiency of bile.

Cross of Descripto, In most cases diarrhora in the consequence. of improper feeding. A very common cause is the habit of giving young children faringerous or biscuit food instead of milk, especially if the child is delicate or rickety. The stomach is easily deranged, and the unhealthy products of digestion entering the intestinal canal excite irritation till ther are eliminated. So far, it is a salutary process, and the diarrhon may soon pass off. Since the use of feeding-bottles has become general, diarrhess is easily provoked if they are not properly cleaned and rinsed out. When this precaution is neglected, any fresh milk that may be put in turns sour and acid. It may be induced by unhealthy nurses whose milk is deranged through privation or anxiety, or when they are suffering from leucorrhom. Impure water, bull air, filth and overcrowding, are also to be enumerated among the chief causes of the complaint. Exposure to cold or heat, and biliary derangement may all lead to the disorder. Very troublesome diarrhos may sometimes be witnessed in children at the time of meaning. The child has probably become badly nourished from the mother suckling it till it is a year old, and then the change of Let to corn flour, mushed potatoes, bread and butter, and even a little most, will cause relaxation of the bowels, restlessness, and thirst; five or six motions will escape during the day, slimy and containing spots of loood. Only a change of diet can set matters right.

Diarrhon is sometimes noticed in connection with rickets, and

it very frequently follows who oping-cough and mentles.

Troublesome diarrhers may be kept up by the indiscriminate

use of aperient medicines.

Transcent.—This will depend upon the cause, which should be if possible ascertained. But whatever may be the origin, and whatever the variety or stage of the disorder, the diet will require immediate and careful attention. Nothing can be done towards offeeting a cure till the age and constitution of the child are considered, and it should be particularly noticed whether it has become anddenly or gradually ill; this question is of immensimportance in the plan of treatment to be pursued. If the child has no teeth, corn-flour, and farinaccous food of all kinds must be forbidden, and milk in some shape be relied upon. If the child is an infinit, and artificially reared, a tablespoonful or two of limewater should be mixed with each bottle of milk, and this will aid the direction of it and prevent it turning non. If there is much sickness, it may be necessary to apply a small mustard poulties to the pit of the stoumch, to suspend the milk for a time, and to give barley-water in its place, and a tenspoonful of cold water occasionally. Too much stress cannot be labd on the importance of feeding, and of selecting the purest milk. When every precaution has been taken with the bettle, in the way of cleanlines. I have known the diarrhoa continue, or the bowels to remain quiet one day and the discharges to be healthy, and yet griping pain, exhausting diarrhors, and sirkness to follow next day. The bottle is alumdoned in consequence, and the child is fed with diluted cour's milk in a teaspoon, and forthwith the diurgious ceases. In some cases Swiss milk has occusionally succeeded better than cow's milk, and that when one wet-nurse after another has failed."

The simple form of diarrhum is consequent upon irritation of the lining membrane of the bowels in the majority of cases, and therefore it is not prudent to hastily check it, as it is an effect on the part of nature to expel offending matters from the system; if after a time the diarrhom continues, a morbid action of the mucous membrane is kept up, which domainds remedies to control it. If it appears to arise from irritation in the stomach or howels, a tempoonful of castor oil, or a few grains of soils and rhubarb, will soon arrest the symptoms and the child will feel no further trouble. In that variety of diarrhom where there is straining with mucus, or mucus with blood, a paste of castor oil; and magnesia, with a carminative will be very useful. If there is

Of uniot.

A temperal for a dose. (An infant may take a flow occasionally.) For children from six to twelve manufacted.

griping pain, and the diarrhesa is profuse, the addition of half a minim of landamam will be serviceable." Castor oil possesses mild and unirritating qualities, and promotes the escape of fluid servicious from the intestinal canal without pain or discomfort. This being accomplished, its subsequent action is said to be estringent, so that at the commoncement it is probably the ratest and best chainstator of morbid secretions which excite the irritation of the bowel.

When the diarrhou is neuto and recent, seething and unirritating diet is especially to be recommended, rice-water flavored with rinnamen, or barley-water, so that the intestines may have all possible rest. Sago, tapices, corn-flour, arrowrest, and chicken broth, are all articles of due to be borne in mind. In older children, where the diarrhou appears to depend on congestion of the mucous membrane, a combination of gray powder and Dover's powder will be useful for a few nights, with bismoth mixture during the day.† I have seen excellent results from this plan of treatment in out-patient practice, even when the children have not been confined to the house. The treatment of summer diarrion has already been considered.

The treatment of diorrhea, particularly in nothicy children, is apt to be looked at with a one-sided rieur,—the quickest way to stop the diarrhem. This is a fatal mistake. If the child is of full habit with florid face and greedy with its food, it is not a good plan to hastily check the diarrhem, but we should simply moderate the alvine losses by some alkaline mixture; and if there are any teeth pressing against the gums, the latter should be

scarified or well incised. Very often the general disturbance and intestinal disorder yield at once to these remedies. Speaking of the diarrhest arising from improper food or teething, Dr. Pavr. writes; "I am in the habit of giving, and with the most satisfactory result, a little ipecacuanha with a hitter and a saline. My presuintion consists of a few minims of the vinum specacuanha, trenty minims or so of the tineture of calamba, and one or two or three drawhms of the Mistura Salina of the Gur's Plarmacoperia, which is made by saturating a solution of earbonate of potash, containing twenty grains of the carbonate to each fluid ounce of water, with lemon-juice. Conjoined with this a couple of grains of gravpowder are sometimes given as an alterative every morning; or nometimes a powder consisting of a quarter or half a gmin of calennel, two grains of the dried earbonate of soda, and five grains of the aromatic powder of chalk." The formula, recommended by Dr. West, containing small doses of vinum ipersonanhe and liquer potasses, is also very useful !

As a rule, astringents are objectionable at an early stage of diarrhees, which may continue in spite of them unless other precautions are taken. If the motions contain mucus and are slimy, and there is any escape of blood, or reduces about the area, chalk mixture, satechu, asida, or bismath, will be of us service; but in their stead the remedies we have already pointed out, especially the caster oil paste and alkalies, with an alternative or solutive, as this case may appear to warmut.

The diet is primarily at fault in these cases, unligested feed larting passed into the lowels, and having excited over-activity of their functions. Warmth and the most complete rest, with a dose of castor oil, is the most appropriate treatment, and a grain of Dover's possiler with a grain of gray powder may be necessary. Now and then a quarter of a grain of calonnel will be found of use in children who are old snough and strong enough to hear it.

Among hospital patients, a large number of cases of diarrhes are traccable to oversuckling, and suckling by mothers in delicate health, or harassed by anxiety. The return of the catameria et even memorrhagia is no hindrance to the habit. If such children are removed from the breast, and cours' milk is given diluted with water, previously warmed and sweetened, the diarrhesa will gener-

^{*} Digotion and in Discolors, 1567, p. 199.

⁺ Ope cit, p. 1881.

ally subside. When milk appears to keep up the diarrhou, barleywater, or oold water thickened with isingless will be necessary, or thin water arrowroot. Sometimes a powder containing two or three grains of rhuburb and carbonate of soda will neutralize the acidity which has resulted from the fermentative products of digestion and soon arrest the disorder."

In some cases where a child is strong, and where there is no abdominal pain, the motions containing mucus or blood, a mixture of sulphate of magnesia, tineture of rhubarb and popparmint-

water may be posseribed with advantage,?

As to attinulants, if there is much exhaustion a few drops of brandy (and there is no better stimulant) in weak arrowrest or milk are advisable, and if there is much sickness, a mustard poultice to the epigastrium. A temporated of sold or iced water will often allay the sickness. Wine whey (one part of wine to three of boiled milk) is useful where the child is exhausted, and life may sometimes be served by it.

In the treatment of bilines discreber, alkalies, especially soda sells, should be given to relieve acidity, with one or two minims of landaness, if there be much pain. An occasional mild mercurial is also servicestice.

Treatment of Cholero Lytration.—In the whole entalogue of infantile disorders there is no disease requiring greater vigilance and care. Any error of judgment is speedily fatal. The child should be contined to a specious stry room, and the utmost quietrate observed. When the bowel discharges are profuse and watery, and the child's strength is good, a dose of castor oil or rhubarb may be advisable, because the cholerate poison, or other offending

materials, will keep up the intestinal discharges, as long as they remain pent up in the system. Elimination through the lowels, consistent with the strength of the child, is therefore a rational mode of treatment.

After this, it is well to moderate the drain, if the child's arough fails, by krameria, or one or two drops of hudanum (Form. 15), and the treatment continued, or modified, according to riveaustances. If lorseness of the bowels goes on unchecked, it becomes a discussed and not a curative process.

When there is vomiting, I have given pressic soid in combination with a drop or two of landamm, or the solution of meriate of morphia; but too frequently nothing has arrested the sickness. It is in these cases that dilute sulphuric acid has been recommended (Form. 31). The fact of vomiting ought not to discourage a plentiful supply of cold water, in very small quantities at a time, or treat-water to allerinte the thirst. If indeed the retching is distressing and urgent, a drink of topid water, by facilitating the escape of morbid secretions from the stomach, is a rational plus to try. In this way the comiting and purging may be arrested in many cases that appear almost hopeless.

As long as there are offensive matters in the howels, it must be our endeavor to get rid of them, as their retention in the body increases the mischief, and therefore opins and its preparation should be given with great caution.

When the disease has passed into the stage of collapse, there is an impediment to the circulation through the lungs, and the remedies for exhaustion, as stimulants and opiates, generally fail to afford relief. The body must be kept warm with flannel or the warm bath, cramps relieved by friction, and a few minims of all volatile or chloris ether administered. If it is considered adsirable to employ a warm bath to encourage reaction, the temperature should not exceed 95° Fahr.; the child should not be sufficiely immersed, but a blanket should be laid over it, and then the child a being also well protected with flannel, can be gradually let down into the water without causing any alarm.

Dr. George Johnson attributes the collapse in cholers to span of the arterioles of the pulmonary artery from an alteration in the Léond, but this does not appear to me quite a satisfactory explanation of the phenomena, when we remember there are conditionallied to this form of sollapse in which the blood cannot be said to have undergone a poisoned state, or the lungs to be specially implicated. On the other hand, some drugs in poisonous doses, and some arimal and vegetable substances have exerted such an irritating action on the stomach and intestines as to produce symptoms resembling cholera collapse." The calibre of the vessels may be influenced by the sympathetic nerve throughout the alimentary canal, and paralysis of the vasomotor nerves would produce dilatation and relaxation of the vessels, the child being thus load as it were late its own veins, and watery discharges are the consequence.

When reaction is established, a few drops of brandy are useful, chicken broth, milk, and the mineral acids are serviceable.

Calonel is searcely to be thought of in those cases, for fear of increasing the general depression. If it is ever advisable it should be confined to the early stage where the motions are fecal, and never had recourse to where the discharges are entery and serous, for fear of increasing the gastro-intestinal irritation. Niconeyer seems, however, to have used it successfully, and Dr. Lewis Smith has seen advantage follow a fractional part night and morning with opium and astringents. "For cholors infantum, if seem tarly, give a hypodermic injection of morphia of suitable dose, to be followed up with small doses of calonel and camphor in sugar of milk, until biliary dejections are seen." (Comegys.) This seems to me, however, a very hazardons measure.

In the treatment of dynamical discretion, Dr. de Havilland Hall advises one or two grains of iperacusths three times a day, and though sickness may at first be produced, telerance is soon established.†

Treatment of Chronic Diarrhou.—If the diarrhous occurs in an infant it should, if suckling, be limited to the breast, and no other food be given whatever, unless circumstances of a grave character should arise, and then it may be necessary to suspend nursing for a time, and give barley-water, thin weal broth, etc. Then, too, the milk of one nurse will keep up diarrhous, when that of another will be easily digested; and it will not unfrequently be found that one nurse after another will fail to supply suitable nourishment to the child, till we have to fall back upon plain milk and water. If this

^{*} On some Analogies of Cholera, etc., Med-Chir. Trace, 1868, vol. ii, p. I, by W. Sedgwick, M.H.C.S.F.

[†] St. Barth, Hosp. Brpts., vol. 21, p. 275.

does not succeed, condensed milk should be tried, as I have previously mannioned. The microscope may detect nothing wrong in the milk of the nurse; and yet it may cause the most violent invitation. Where milk disagrees to such an extent as this, it is obvious that some other means most be adopted for a time to upport the child. For children who have reached five or six mostla old, veal broth, or weak heef test or naw meat Julce, may be tried, if the milk appears to keep up irritation. As the child grows other it will be able to digest better, and then the discretion of the practitioner must be used, and the diet varied according to circumstances. As long as the stools are unhealthy, or pasty, all farinaceous food must be given with caution, as it will frequently pass through the stomach undigested.

Too much importance cannot be attached to the feed. It is of the highest consideration that it about he pure, nutritions, and unirritating. Where there is defective nutrition the child will gradually waste, and the more exhausted it becomes, the more difficult will it be to overcome the diarrhera, which is prose to go on in spite of all the pharmacentical remedies in vogue. Hence it is that row most juice sometimes answers so well in these cases. It may be made of beef, or muttou."

With regard to drugs, it should be remembered that there is a great tendency to addity of the secretions; excess of acid in the stomach retards the digestive power, excites fermentation, and causes flatulence, rain, and irritation, so that the child is never easy, and can obtain no rest. Potash, by neutralizing the acidity, arrests the fermentative process, and it may be given with dill, anisced, or common-water, three or four times a day after fielding. If the stools are thin a mixture of bismuth and potash, or sods may be given (Form, 25). As long as the motions are sorid and offensive one of these remedies should be prescribed. Sometimes a grain of Hyd, c. Cryta may be most advantageously added to a powder of soda and rhubarb. Inconcumba in doors of a quarter of a grain, with the castor oil mixture and haslanum (Form, 24), is an excellent remady, particularly in the dysenteric variety. Creasote has been employed successfully where the motions are frothy and fetid. A chronic diarrhau is oured or kept in check by gallie acid or acetate of lead, recommended by Dr. West (Form, 28, 29). not answered my expectations, and I have been so frequently disappointed with it that I now seldom employ it. The syrup of red gum, combined with nitric acid and logwood (Form. 35), or with the extract of back, are all useful (Form. 36). A dose of castoell paste (Form. 23) may be needed to remove irritant matter from the bewels, and especially in those cases where exposure to cold has chilled the surface and increased the congestion of the internal organs.

Sulphate of copper is another remedy to be employed with spinm, and a few drops of spirit of chloroform in special cases

(Form. 37).

In very obstitute cases onemata of starch and spinm may be tocourry. I found no remedies administered by the mouth check the nivine discharges so effectually as one used night and morning in a case depending on mesenterio disease. In very obstinate cases Tromoseau employs an onema of one grain of nitrate of silver dissolved in an ounce of water. In the dysenteric distribute of children, Dr. Ringer speaks favorably of salicylic acid used as an injection (1 to 200).*

This chronic diarrhus indicates a relaxed state of the system generally and loss of tone. A tonic regime is consequently required, and frequently gives relief when other remedies have failed. Thus, change of air, by altering the surrounding circomstances, is often of incalculable benefit. Removal to the senside, or some dry and healthy locality, will accomplish more than any drugs when the case has assumed a chronic character and the bowels are bregular in their action. Cold baths in the morning, or if the fittle patient be very feeble, boths with the chill taken off, with friction and elumpeoing, tend to brace up the relaxed tissues, Benefit is frequently obtained from the use of cod-liver oil, steel wise, malt extract, and other remedies of a similar invigorating character. Every case of diarrhosa demands cure, from its hability under neglect to lead to the server forms we have described, or to originate mischief in the brain, or tuberele, or marasmus, as the general strongth becomes more and more reduced.

Prologous Asi.—In cases of long-continued diarrhers the sphineter and loses its contractility, and the surrounding parts become relaxed. When the diarrhors is cured the local irritation ceases,

^{*} Handbook of Therepoutice, 5th edition, p. 579.

and the child's bowels may not oner or twice daily without my protrusion of the rectum. The treatment consists in spenging the relaxed parts with cold water, and if there is tenesus as opiate enema after the horsels act will be of service. Another plan is to wash away all feeal matter from the gut, and then apply a strong solution of alum before it is returned. When the gut remains protruded apart from any action of the bowels, gestle pressure with the finger dipped in oil will cause it to return. Cold water enemata every morning are serviceable in this state of relaxation. I have found great benefit from the use of sulphate of iron and infusion of quassia as a valuable astringent enema," and the decoction of tormentilla has also been recommended. Where the prolapens and is not the result of diarrhox, but is rather a chronic condition, it is well to hold the child in the hands whilst the bowels are being relieved, as, by so doing, the gut will rarely he forced down. If, on the other hand, the child is placed where its feet can reach the ground, it will make such powerful expulsive efforts as will commonly cause protrusion. Another plan is to keep the little patient lying on its back whilst the motions are passed. A compress and bundage may be wors during the day to prevent descent.

CHAPTER XVI.

GASTRITIS-MELESA-DYSENTERY.

Gartington Symptoms Comment transmiss. Supported on the Stronger Street and comme Hamartenesses and Milleria; Comment-Symptoms and freshold. Discovered: Symptoms Comment Pathology and freshold.

Garrarys is of rare occurrence in children, and the symptoms are too obscure to enable us to diagrams the disease with any approach to certainty. Cutarrh of the gastric uncous membrane (gastritis macrost) has been referred to active hypersenia; it occurs in the case of drunkards, as well as in chronic heart disease and pulmonary phthisis. The anatomical changes in this state are a

dark-reddish slate-gray discoloration of the mucous membrane, spots of ecchymosis, and a general hypertrophy of the parietes of the stomach.* The disease may be induced by irritating articles of food, and by swallowing corresive acrid substances, or from any causes which excite indigretion or flatulence. The stomach may caliblit the celdence of gastric catarrh after death in those children who, during life, have had no symptoms of the disease, nor even disturbances of digestion.

The symptoms are distension and pain at the originatrium, increased on pressure, vomiting of a glairy more or greenish secretion, and constant retching after food. If the disease goes on the shild becomes thin and constitted; there is thirst, and the tengue is covered with a thick white far; the pulse is frequent and small in neute cases, and there is constipation alternating with diarrhom; but a subscute form of gastriris may be present, giving rise to no more symptoms than are ordinarily to be met with in initiative dyspepsia. If this continues the nutrition of the child suffers, and it losss flesh and strength.

The treatment consists in giving mild water and sedatives after a cureful regulation of the diet. Whilst pain and sinkness continue, milk in small quantities at a time is the best form of nourishment, and it may be necessary to add a little lime-water to assist digestion. For the rulief of the profuse gasaric secretion, Vogely recommends half a grain of nitrate of eliver in three ounces of water as a mixture, of which two tenspoonfuls may be given to children from one to two years of age. For older children he gives a sixth of a grain of nitrate of silver.

But gastricis, of a subscute character, deconds that bland and non-tritating food should be taken, cold or iced water to allay thirst, and bicarbonate of potash and hydrocyanic acid as a solutive to the morous membrane. If there is much irritability of the stounch, a grain of colonel, with a few grains of tragacauth powder, divided into six parts, and given in the space of twentyfour bours, will be a serviceable remedy. Poultices stay be applied to the opigastrium if the pain does not yield to the remedies mentioned, and enemata are preferable to purgatives.

In cases of gastritis produced transmittently the best treatment probably is that of opinm and hismath:

^{*} Hokitansky, Path. Ann., vol. 7, p. 257.

[†] Diseases of Children, 1874, p. 141.

Squeeley of the Stanoch.—It is most important not to mistake
the appearance found in the stomach after death, from the action
of the gratric juice, with those that result from disease, or the
introduction of irritating substances. The experiments of Hunter
showed that the gratric juice after death was capable of diseaseing the conte of the stomach, more especially in these persons who
had died suddenly. As many individuals were quite well up to
the time of death, he believed that these changes were caused by
the action of the gratric juice after life was extinct.

In some instances, the process is limited to the nucous membrane, which is softer than usual, and breaks down under slight pressure of the finger; in other instances, the morbid change is greater, and it extends through all the coats, by means of a soft irregular nicer, the contents of the stomach escaping into the pertenest cavity. The diseased process most frequently attacks the fundus of the organ, where the fluids gravitate, and the bloodyessels ramifying over the coats of the stomach are dark and congested, producing a condition resembling chronic inflammation. Adherent to the interior membrane may be seen an opaque or brownish tenneious mucus, which is easily removed on pouring over it a slight stream of water.

The disease appears to be not uncommon in infancy and early life, when gustric disorder is so frequent, but I am not able to refer to any symptoms, either in my own experience, or that of takes, which would emble us to say during life, that softening of the stomach would be found after death.

Softening of the intentions has also been mentioned by writers on medicine, the mucous trembrane becoming actioned or destroyed down to the peritonnal investment.

Homotornia and Molane Vevs.—Infants of a few days off suffer occasionally from vomiting or purging of blood, sometimes from both. "It is essentially a disease of the early days of life, generally occurring between the first and sixth day." Dr. Raha Escher considers that the homorrhage is greatest within the first twenty-four hours of life, usually ceases on the second day, but may continue to the fifth, or even later.

Courses.—In many cases it is impossible to find out the source of the hemorrhage. Various opinions have been offered as to the cause of this rare and obscure condition. The disease would up-

^{*} Dispuses of Infrare and Childhood, by T. H. Tomer, M.D., p. 116.

pear to depend chiefly on the physiological changes which take place at birth, when respiration becomes established, and the langs, fiver, speem, and intestines are liable to become congested through an increase of pressure on the venous system; hence one reason, probably, why convulsions are frequent after birth in delicate children. Tedious labor and the pressure of instruments are mentioned as factors in the production of the hemorrhage. Some cases are an record which show a hereditary tendency to bleed in the parents."

Of twenty-two cases recorded by Billiet and Earthez, twelve recovered. These were probably cases of pressure of the child's head during tedious labor, and congestion of the venous system from a difficulty in establishing respiration at birth. ["Taking the cases altogether, the mortality is about 60 per cent." (Crosm.)

Poblogy.—Some authorities consider the hemorrhage as a crisis of the pletheric condition, and such cases would appear to be by no means uncommon in the newly born, there being general congestion of the integraments and chief internal organs. Cases are recorded which show that it is sometimes due to blood change, as in purpose hemorrhagica. Bouchut quotes from Billard (p. 497) the case of an infant, five days old, whose trunk, limbs, and arms were covered with violet petechie, and the yellowish spaces between them (from the slight joundice which was present) gave the surface "a tiger-like aspect." After death, dark blood was found in the intestines and stomach, the spleen had ruptured from over-engagement, and the heart was full of blood; the cellular tissues contained large eachymoses, as did the kidneys and bladder; the pleane presented petechice, and the brain was congested.

After death, in ordinary cases, the internal organs have been found exanguine, but healthy. Spengelberg and Landau report cases in which abscesses were found in the duodenum, arising from embolism. Cases of this kind never recover.

The quartons are prestration of the strength, pallor, rapid breathing, inability to suck, small pulse, and occasionally convultions. Cases which survive the shock may end in diarrhous, hydrocephalus, or mesenteric disease.

Meleca Nessacovan, by J. Halliday Crossa, M.H., Med. Times and Garces, Oct. 234, 5400, p. 480.

I Torité Charges et Pratique des Maladies des Enfans, Paris, vol. il. 1850.

f. Malerer Neumbourn, by J. Halliday Croom, M.B., Med. Times and Gamtin, Oct., 251, 1880, p. 480.

Blood drawn from the nipple in suckling (quarious feronteness) must not be mistaken for true bematemesis.

Treatment.—This is unsatisfactory and uncertain; little, if anything, can be done. Astringent susmata with cold water when the homorrhage from the bowels is bright and active, or even cold applications to the abdonou, may be suitable in some cases. When faintness and exhaustion threaten, ammonia, ether, etc., will be required.

Dysentry.—Young children are sometimes seized with this disorder, but it is very rare, and it is not improbable that intestinal bemorrhage has been mistaken for it. When the stools are sliny and contain more, there is an alteration in the intestinal nuceus membrane, and, if it hasts, more or less blood may be mixed with them. In some chronic cases the evacuations are little more than lamps of blood and mucus, dark in some instances, and pink or bright red in others. In aggravated cases, the bowel discharges are so altered that they become offensive, and of a slate-gray has from containing portions of mucous membrane which have slonghed, and there is a discharge of pas, indicating the pessence of alcoration. Dysentery may begin as a primary disease, or commence as simple diarrhors, and depend upon the same cases; the inflammatory form of diarrhors (setero-colins) is closely connected with it.

The spacetoss resemble those of entero-colitis, but are more severe; they usually begin with violent sickness and comiting, when the disease is neute, accompanied with shivering and palon. The motions at the caset may be copious, and for the first few days of a bilious character, then they become more scanty and slimy, with glatry muchs resembling white of egg, and mixed with blood. Sometimes pure blood escapes, but generally it is mixed with the focal matter, which now and then escapes in lumps, cousing griping pain in the abdomen, tenesmus, emmps in the thighs, and difficulty in micharities. There are abdominal pain and tenderness in the course of the colon, and frequently around the navel. Favor is solden present unless the distant lasts some time, when the skin becomes harsh and hot, and the pulse frequent.

When the disease assumes a chronic form, the child becomes emaciated, and the bowel discharges are mixed with per and blood; there are pieces of lymph in the motions, which are very acrid and offensive. The child is restless, and cannot sleep at night from pain and tendernoss; there is gradual loss of flesh, prestration of strength, constant thirst, nausea, and disinclination for ford. "Of thirty six cases, the termination of which we have recorded, four proved fatal," (Meigs and Pepper.) The complaint may terminate in peritonitis and ascites, in mesenteric disease and lastic fover, or in a sudden fit of convolutions. When the disease is progressing towards recovery, the evacuations become less frequent, and blood no longer appears in them; the child ceases to be feverish, and rests at night, whilst the appetite returns.

Counce.—The disease is more frequent in but summer weather, when suripe fruit is eaten, and bowel disorders are rommon. Improper feeding, defective ventilation, seastly clothing, impure water, and exposure to cold and damp, are all capable of originating the disease. The influence of malarin, too, is to be reckoned as a cause, as well as the exauthemata, particularly measles and varieta (Meigs and Popper), and diseased intestine from typhoid.

Pathology.—In the neute stage of the disorder, the morbid changes are to be seen in the large intestine and rectum, as in entero-colitis. It resembles this disease, except that the changes in the rectum and colon are greater, and it often exists in an endemic and epidermic form. In some cases the small intestines are involved; the purcous membrane is swollen, soft, and reidened in patches or throughout its entire length. In some places it may assume a dark or gangrenous appearance. The follious are calorged. In the more advanced or chronic stage, small reund specks of observation form, which finally run together, and produce a ragged uneven appearance, varying in extent and depth. The mesenteric glands may be natural, or slightly enlarged and rel. In long-standing cases the observable occurs contracted, and surrounded by hardened tissue.

Freeburst.—When the disease is recent, and sets in with acute symptoms, a warm buth is of great service, followed by poultices to the abdomen. The most absolute rest and warmth are demanded, and, if there is no vomiting, the enstored pasts (Form. 23), with a drop or two of landanum, will be necessary to administer in order to clear the bowels of any scybalse (Form. 24). If there he tenesmus and straining, an optate clyster will give great relief. In some form or other opium is the most valuable remedy

we possess in this complaint, as it controls the action of the bowds, allays pain, and procures sleep. Acetate of lead, catecha, krameria, sulphote of copper (Form. 2), 31, 32, 37), will at once come to our aid in turn, when the bowels continue obstinately irritable.

When calonel is employed, it should be given in very small doses at an early stage, is combination with opium or Doser's

powder, but its use requires extreme cantion.

Nitrate of eilver has been recommended, in combination with a few drops of optime, given in some suitable vehicle, like muclage or syrup. The eighth of a grain may be given to a shill two

years old every three or four hours.

As regards diet, if an infant, it should be kept to the brent, and no other form of food given. Older children may have barkywater, sago, tapicen, rice-water, etc., as mentioned under the treatment of chronic diarrhers.

Symptoms are fixed resease two Printed Printed Printed Course of and and system—The of second Bat position—Battalance—Bylorie of object and branch of printed course.

Construction is one of the commonest disorders of early life.

When it occurs in infants it is a source of much trouble to the
mother, who is sorely tried with the difficulty, because the child
cannot thrive without a frequent action of the bowels. The
younger a child is the oftener should the bowels act. In infants
they are moved three or four times a day; and in children over
one year there are generally two evacuations daily.

Among children artificially reared, constitution is a frequent nilment, particularly if they are feeble. There is deficiency of intestinal secretion, so that by the time the motions reach the large intestine and rectum they are extremely hard and public, and the child eries and undergoes painful straining to evacuate the hardened masses. Rest is not obtainable at night from flatulence, the belly becomes awellen, the logs are spasmodically drawn up, and then stretched out again. If this state of things is suffered to go on, the child may have a convulsion, or die worn out withpain and exhaustion. An accumulation of gas in the intestines may occur in these cases, especially where the secretion of bile is scarty, and those articles of diet are indulged in which cause fermentation. When the amount of mucus is sparingly secreted, the muscular fibre fails to projed the contents of the bowel, and hence constipution is common in such cases.

The color of the fieces depends upon the admixture of like, and the motions may be brown, green, or almost black, or like elay, When bile is deficient, the motions are pale; ordinarily ther are of a gingerbread hac. "The consistency of the feces also varies considerably; they are figuid when the serous exhalation of the mucous membrane is excessive; somified when the secretion is muco-golatinous, or they are mixed with the secretion of the shape of grunious particles. The feenlent matter found above the various intestinal strictures presents a psonliar frothy appearauco." Constitution, too, in older children is sometimes caused by starch compounds, as rice, arrowroot, tea, astringent and tonic mixtures. And, according to my experience, it often originates in the neglect of parents to inculcate the habit of getting the lowels to act at stated hours. Constitution is also a frequent accompaniment of cerebral disease, as meningitis, hydrocephalusmarresous, in consequence of a loss of tone in the moreular fibre of the intestinal conta-

Constipation is likewise observable in children with sluggish livers, who are not otherwise ill. The complexion is sallow and the appetite expricious, the motions are pule and contain scarcely a trace of bile. The tongue is coated, the urine scanty and high-colored, and hendache and lassitude are also common. These symptoms often arise from overfeeding and eating greedily.

I have elsewhere alluded to constitution as the consequence of hernis, intrasusception, and intestinal obstruction.† Imperiorate anns is another cause.

The symptoms generally met with in constipution are distension

^{*} Boldersky, Path. Austony, vol. ii, p. 110, Syd. Soc., 1811.

[†] See Chap: XVIII-XIX.

of the abdomen from tympanites; the bourds having lost their contractile power, expand and push up the liver, stounch, and apicon, thus interfering with the descent of the disphragm. In these cases the abdomen after a time bosomes painful, and the child is restless, the tongue is furred, the mouth bot, and there is sometimes veniting.

In many simple and uncomplicated cases, the symptoms are not so marked, the abdomen is more or less tense, and there are scamp dry evacuations, heaviness of manner, loss of appetite and thirst. Halistnal constipation may cause convulsions in young children.

Whilst constipation is most common in delicate children, especially if brought up by hand, it is of frequent occurrence in strong shiften who are so reared; and hence I am inclined to credit injudicious feeding as a cause. I have over and over again seen the strongest and bost-developed shiften an attacked; they are plump, bright, and healthy-looking, the only allment being a painful straining in emptying the bowels. Now, in these cases, although the skin is of a normal har, and the conjunctive of pearly brightness, deficient biliary secretion is the essential cause of the crid; and until the liver pours out more tide, there is no probability of relief. When the liver has been stirred up by a mareurial pargative, the bowels have become regulated, and a recurrence of the crid has only happened with food, improve in quantity or quality.

Treatment.-No remedies will be of any use till we have assetained the cause; and the first step to take under any circumstances will be a proper regulation of the diet. To prescribe drugs till this is impaired into will be a fruitless proceeding. Milk ought to enter largely into the distart of roung children and weak animal broths in place of mucilaginous and starchy foods, with a liberal allowance of cold water. If the child is old enough, Scotch eatment with milk once a day is an excellent remedy to keep the bowels open. The oatment and treacle biscuits made by Scotch createstioners and lakers, or the so-called "Yorkshire parkin," is a famous aperiont food for children. These bacuits may be procured of Macalpine & Co., 287 Oxford Street. Pruses and senna are also serviceable, and if in season, a few grapes or a baked apple may be allowed. In infants and children of a few mouths old, the castor-oil paste is a safe aperient (Form, 23), relieving the flatulence and exciting the action of the bowels. The

œ

syrup of rhuburb is another good remedy, and manus is a safe and mild laxative which infants take readily. Manus may also be given in the form of posts with a little cream of tartar. A suppository of common yellow scop introduced into the rectum at might will sometimes cause the bowels to not naturally in the early morning. A child delicate from birth suffered from constipation, passing motions resembling city marbles in color and shape; it was never easy day or night. All treatment failed to give relief till at six months old, malt extract, mixed with milk, was tried, and in a very short time the motions became natural and the bowels regular.

In older children I have known treach and head insure a daily and regular action of the boxels. In some strong children where febrile disturbance and best of surface attend constipation, a few grains of sulphate of magnesia with cincumson, which disguises the taste, will answer extremely well, or (Form. 8), regulating the dose according to the age of the child. If the complexion is sallow, the urine turbid, or if the motions indicate a deficiency of bile, a little gray powder with rhubarb and blearbonate of soda may be given with advantage for a few alglits, and a situate of potash mixture during the day. In some cases, if the belly is turnid and the hopatic secretion habitually defective, small dose of the perchloride of mercury may be ordered with fincture of circhona and taraxacum. I have also seen excellent offects fellow the administration of nitrobydrochloric acid with taraxa-

com? where the liver is singgish, and the child is torpid and pale, and made a tonic and alterative at the same time. The Pale, Glycyrchize Co. (Ger.), which contains sulphur is an admirable aperient for children, and is not disagreeable to take.

Lastly, there are cases repeatedly mot with where it should be our object to give as little specient medicine as possible by the mouth, because the constitution depends on a laxity of the intestinal fibre. A judicious combination of belludeans and strychrin is to be recommended in obstinate constitution, but if in spite of these remodies and diet, the lowels remain persistently contive, a two-conce opens of warm soap and water will rouse them to activity, and render soluble the focal masses which are ledged in the descending bowel and rectum. This may be used for infants and children of any ago.

In every case of obstinate constipation, the finger well ciled, or an elastic tube should be passed up the bowel to ascertain if any hernia or mechanical obstruction exist, for if it does, all treatment

by the month will be unavailing until it is removed.

Experience, however, teaches us the danger of too netire interference in cases of constitution, unless urgent symptoms are present; the bowels may be torpid for days or weeks together in exceptional cases, without danger to life. †

Then repeated apartition broads

Cole is a common complaint in young children. It consists in painful contraction of the intestinal coats, and is caused by the accumulation of hard focal matter in the bowels, or some irritant food, or substance lodged in the intestines. Slight attacks in infants are not uncommon from accessive aridity in the stomach, forming milk into a hard indigestible curd. In children it in frequently induced by eating unripe governeries or other indigestible fruit, and drinking large quantities of cold water when the stomach is empty and the body heated. Worms in the bowels, internal strangulation, or obstruction are severally capable of causing the disorder. Colis often accompanies diarrices in young children. Exposure to cold is matther cause, and so is bathing in too cold water.

The symptoms are sudden twisting pain in the abdomen, generally in the direction of the transverse colon, and coming on in puroxysms. The child draws up the legs and bends the body forwards to relax the abdominal muscles. There is generally flatulence, but the suffering may be intense, without any distension whatever, and with even retraction of the ambilious. When the gas which is naturally formed in the stomach and intestines is not expelled by the anus, then the delicate muscular structure of these organs yields, and the abdominal wall becomes distended and tense. typhoid fever and some other affections in which the ganglionic system is severely implicated, there is a drumlike distension of the intentines (meteorism) accompanied with quick shallow breathing, and increased action of the heart. The abdomen is not equally distended; it may be conical along the centre, and the small intestines be more involved than the selon in certain cases. I believe that in the latter class, focal matter or undigosted food is the chief cause of the pain. In addition to the symptoms just enumerated, the child shricks out with pain, the angles of the mouth are drawn down, and the face is pitiable. Syncope and even convulsions mar happen in severe cases.

The disease is to be distinguished from peritoritis by the anddenness of the pain, and the freedom from suffering between the paroxysms; by the quietude of the pulse, the absence of fover, and the relief obtained from pressure. Most practitioners must

year hard and feed matter, like hard cinden, and non-nelland the any of the abdances to that of twesty-six inches in circumfracture.—Path. Truss., vol. v, p. 174; also Holmer's System of Surgery, loc. etc.

have observed children when pale with agony, throw themselves nerces a chair to obtain the relief which that pressure affords,

Transcal.—If the case is one of simple colle, and we combler
the pain to be due to nonscalar contraction, it will be advisable to
keep the bowels quiet till the pain is relieved. To attain this end,
flancel wrong out of warm water should be applied to the abdonion or repeated poultiess. I have found a mixture of carbonate
of impressa and spirit of chloroform with peppermint-water very
serviceable, particularly if the bowels are distended. When the
pain is mitigated, and we think it is desirable to act upon the
bouch, a dove of costor oil with tineture of opinm and two er
three minims of spirit of chloroform will be indicated. In infants
at the breast troubled with colle, it is often well to give the
mother or noise some carbonate of magnesia; in other cases,
where the milk is too firmly cardied by excessive acidity in the
stomach, and who "possett" a portion of this cardied milk,
eapput oil with potash is useful.†

A copious injection of warm water with a little oil will often produce speedy relief. When colle scenes to arise from indiposible matter in the stomach, an emotic of spentenanha may be given.

If there are symptoms of obstruction, they must be dealt with in accordance with the instructions under that loading; I enemate may be tried, and if these fail, the little patient must be kept under the influence of opium and helindonna. The latter drug is said to be very serviceable in the colic of children. Hydrate of chloral and bromide of potassium are also useful, by relieving spasm and inducing sleep.

CHAPTER XVIII.

INTESTINAL OBSTRUCTION.

Circus: Intercorption—Food accomplation was foreign before. Hereign Mafferman, of notion and near—Directions and compared accomm. Created records of their afferman.—Direction of recorptions of their action. The arms of the Relation of any bound production. Medicated action to discuss the hand. However,

By obstruction of the bowels is to be understood an interruption to their functions, arising either from causes acting from without, as in hernia or volvulus; from within, as in feud accunulation; or directly implicating the walls of the intestine, as in stricture.

Intracescoption is the most frequent cause of neute obstruction in childhood."

Next to this, hernia is not uncommon in children as a cause of obstruction, but the protruded intestine does not often become strangulated before adolescence. In obscure cases of obstruction, before resorting to extreme measures, it is advisable that a surgeon should examine the abdomen in the regions where hernia may occur. Mr. Howard Marsh tabulates forty-serves cases of strangulated hernia in children, giving as full details as he could gican from the original records of each case. This valuable table necompanies a paper in which the author discusses the subject at length.†

In cases of obstruction in new-horn infants the practitioner may find that he can pass his little finger into the anns. That being the case he must still bear in mind that the rectum may be imperforate some distance above the anni operture.

The most puzzling forms of acute obstruction that are met with in childhood are those due to certain congenital muliformations of the intestinal canal. From time to time such cases come under the notice of the physician.

In children and adults no trace can be found, as a rule, of the fetal omphalo-mesonteric duct. But it sometimes remains as a diverticulum from the ileum.; Close to this abnormal outgrowth

[&]quot; See Chap. X1X.

[†] Reports Ulasanning the Surgery of Childhood, St. Bartholomew's Hospital Reports, vol. x.

² For the anatomy of this condition, see Strethers, On Diverticals from the Small Interdes, Edia, Most, and Sarp, Journal, 1894.

the intestine itself is often very narrow, not from any morbid deposit in or outside its coats, nor yet from alteration and cicatrization, but purely from ill-development.

An interesting case is recorded of "intestinal obstruction cannot by a hersin through the mesentery of a Meckel's diverticulum, which had retained its attachment to the umbilions." The patiest, a loy serve years of age, was seized with severe pain at the unbilieus, relieved by the sitting posture. He had necasionally suffered from attacks of pain. Vomiting set in on the third day, and continued with varying severity throughout the illness, but it was never feeal. The urise was sounty, and of high specific gravits. Paroxyems of pain occurred from time to time, and enemata brought away fecal masses. The pain abated on the fifth day, but on the following, increased distension of the fully took place. and he died. After death, commencing peritonitis was discovered, and "about two feet of the lower part of the Henry were found hanging in a collapsed condition on each side of a cordlike loop. This loop was formed in the mesentery of a well-developed diverticulum, the upper end of which was attached to the umbillem by an impervious cord half an inch long, the diverticulum itself being four inches in length. The gut, where it passed through the loop, was constricted and puls, but a small projecting portion at the origin of the diverticulam was of a deep purple color." Two eases of fatal obstruction, one in a girl of thirteen, are recorded by Dr. Souther, from congenital constriction of the gut, at the point of departure of diverticula, the remains of the omphalo-a esenteric duct.t

Very frequently the diverticulum itself is the cause of mischiesons or fatal complications. It may adhere to some part of the abdominal wall, and drag the intestine to such an extent as to completely obstruct it. This occurred in a child of ten, in by. Wilk's experience. Sometimes the diverticulum becomes all becaut by a hand of lymph to the mescutery, forming a loop is which a knuckle of intestine may become strangulated; this has been observed in a child aged four. In other cases the diverticulum may become filled with foreign bodies, or undigested fool,

⁴ Haliste's System of Surgery, rol. by, Art. Discous of the Intestine, by George Pollock: Eq., p. 410.

and fatal obstruction with perforation of the machid outgrowth may ensure as in a specimen exhibited before the Pathological Society."

Diverticula may become perforated in typhoid fever.

A displaced appendix vermiform's may become united to the bowel, forming a band, and ultimately causing obstruction.

Mr. Pollock, in his article on diseases of the intestines, in Holmes's System of Swegery, after enumerating the signs of intessusception, then proceeds to describe the symptoms of these carer forms now under our consideration.

"In all internal strangulations by bands, etc., the symptoms are generally very acute; the pain is sudden, sharp, even agonizing occasionally; vomiting sets in early, and is usually incressant; the distension may not be as great as in the more slowly operating causes of obstruction, since little food can be taken, but still the small intestine becomes much loaded; there is generally great tenferaces on pressure, for usually peritonitis is not long absent; there is early oridence of grave constitutional damage, for the portion of intestine, tightly bound down or encircled at the strictured part, soon thickens and inflames, or may blacken and nortify."

As for chronic obstruction, the physician should be on his guard in watching all disorders in which it may take place. It often accompanies intractable tubercular disease of the peritoneum in all-fed children.

² See Chapter XVII, On Consequition and Orlic.

A case is recorded where a child three days after hirth had passed no motion. As the finger could only be introduced an important the rectum, the case was looked upon as one of imperforme anne, and an operation was performed. Two days later, the child died from peritonitis. A post-mortem examination showed that the obstruction was due to a volvalus situated two feet above the ileo excal valve."

CHAPTER XIX.

INTUSCOLETTON -- INTAGENATION,

Meaning and Derivations: Two forms described—1. Sough interesciption, slight at a particular—Case in the response —2. Source or inflammatory forms. A particular the response of the control of the response of the control of the response of

Invagination belongs particularly to infancy and early life, and is one of those disorders that demands prompt and judicious tentiment. Fortunately its frequency bears no relation to its invariable pointhdness and danger. This malady essentially consists in the passage or inversion of one portion of intestine into another, justin the same way as one tube may be slipped into another, or, what is a better illustration, the end of a glove-finger or stocking pushed within the upper portion. The effect of this lavagination is not primarily strangulation, or arrest of the circulation, but obstruction to the passage of the intestinal contents. Sir Thomas Watson observes, however, that "the contained portion of intestine is liable to be nipped and strangulated by the containing portion, and all the peril of hernia results, with much less chance of relief by art. This state of things is called intussusception."

Intussusception may be divided into: I. Simple, slight, or spasmodic cases, where the invaginated intestine has not been

Brit. Med. Journ., vol. i, 1884, p. 738.

[†] Principles and Practice of Physic, 1887, vol. i, p. 48.

sufficiently irritated to become inflamed. 2. Severe cases, where the involved portion has inflamed or sloughed.

The first variety is unutrended by inflammation, and may be considered mainly due to spasm. A good example of this will be described presently. Slight intumusceptions have been found to the bodies of children who have had so symptoms of such displacement during life, and who have died from other forms of disease. Integretation of the small intestine is not unfrequently found at the autopsies of children who have deal during the period of dentition, or from diarrhou, without any symptoms of intusesception." Billard has seen it in excess of constipation, and Levia Smith in infants who had had subarute se chronic enters-colitis. "It is the result of an unequal irritability of the intestine, and the consequent irregularity of its movements, and it is, therefore, frequent in diseases characterized by torpor of the cerobro-spinal erstem, and in the mortal agony proceeding from them; whereas It earely or never notices in discuses accompanied by, or ending with aldominal paralysis, such as chotera, typhus, general peri-Louitis, etc.

The introduception in some races is slight enough to make it probable that no trace of inflammation or even congretion is present. The invaginated mass is usually from half as inch to two inches in length, and, as a rule, this accident is multiple. There may be ten or more distinct introduceptions at distances of a few inches from each other. In the museum of the College of Surgeons there is a specimen of a portion of the small intestine of a child four years of age, in which three intusprescriptions are to be seen all close to one another.

An introduction involves three layers of intestine. The innermost consists of the invaginated upper portion of intestine; its nurcons layer is internal and the peritoneal external. The middle or inverted portion also belongs to the invaginated segment, and is reflected below from the lower limit of the inner layer, and above is continuous with the upper margin of the outer layer. From its inversion the mucous membrane lies external to its peri-

[|] Rebitmely, Purk, Auctory, 1949, vol. 5, p. 54, translated by E. H. Sierching, M.D.

¹ No. 1265, Pathological series.

toncal coat. The outer layer consists entirely of that portion of intestine into which the former two have intruded themselves. Above it is reflected upon the middle layer, with which, in fact, it is there continuous. Its mucous surface is innermost, faring that of the middle layer. "The inverted partion is invariably the one that suffers most; the inflammation of the entering tube is less considerable, and it is characteristic that, even when the inflammation of the volvulus runs high, its mucous membrane remains rule; the sheath of the volvulus also is but slightly affected in small intrassucceptions, with the exception of the peritonitis at the rollar where it enters." "The vessels of the portion of intestine thus incorporated become engarged and render the obstruction complete; the whole of the folds involved become swellen and deeply congested; Idool is extravasated into the substance of the morous membrane as well as into the meantery; in a short time both the serous and minimus surfaces become inflamed and the effusion of lymph takes place; the opposed serious parfaces become adherent, and also, to a less degree, the mucous surfaces; Moods serum and mucus are effused into the canal, and this discharged per rectum is very diagnestic of intresasception."+

The following I consider to have been a typical case of the spasmodic variety, unattended by peritonitis, or actual constric-

tion, and terminating in complete resovery.

E. S.—, at 2 years and 9 months, was first seen by me on January 4th, 1875, at 10 a.m., having been in good health the previous day. She was an intelligent and precedent child. I found her in bed, very flushed and excited, skin bot, but aweating. Temp. 103°, pulse 180, respirations quick and shallow. She by with her logs extended, and here pressure over the abdomin with the hand without complaining. The helly was rather sympanisis, and the bowels constipated; they had acted scantily on both the two previous days; there was thirst, but no vomiting. The child was allowed to drink a little milk and iced water at intervals to allay thirst. The abdomen was fomented, and half a grain of calomel ordered every four hours, together with citrate of potash.

January 5th (10 a.m.).—The child had been sick once, and the bowels not having acted, her mother used a simple enema of warm water, which returned as injected. She oried out occasionally with

[&]quot; Bokitmeky, Path. Austency, p. 17.

⁺ On Discuss of the Alinestray Canal, by 8, O. Habershor, M.D., 1857, p. 225.

pain, but no distension or tumor can be felt. Has taken two powders, and kept both down. The sixth of a grain of calousel, with one grain of Dover's powder, was ordered every four hours. (7 r.st.) Desing, and no return of sickness. Having passed no urine, a gum elastic catheter was introduced, and six onners of clear urine drawn off.

6th —A good deal of tenderness over stomach and neighborhood of umbilicus, but no vomiting. Eight onuces of warm scap and water were thrown up the bowels, which brought away a little feculest matter. A carminative mixture of rhuburb, aromatic spirit of ammonia, and peppermint-unter were submituted, and ordered every four bours in place of the powders.

7th (10 a.m.).—The bowels not having zerod, and there being no certainty of obstruction, I gave a lozenge of scammony and gr. § of calonel, which had the effect of causing considerable pain and uncasiness, without producing any execuation. The child again could not pass urine, and on that account a cathotor was introduced into the bladder, and seven onness of clear acid urine drawn off. The finger inserted into the rectum was unstained by feed matter. I now determined to keep the bowels at perfect rest, and ordered the following mixture:

R.	T. belladon	mer.		-		-				8	Maj.
	Spt. chlore	lan	4.4	-	-		- 0	-		3	3(ti)
	Arid lyde	00%	401	4	- 0	4	- 1			-	Rivi
	Syrepi,	9	-		1	-					340
	Agents ad						1	8		3	3 mM.
50 seery four hours.											

(3.30 s.m.). The child was dispered to be drowsy, and the muscular system was much relaxed; great tympanites over stomach, and above line of umbilities, but nothing marked over either iline foss; lips rather dry, and tongue creamy; has kept down milk and water and beef ten during the day. Urine again drawn off, less in quantity and deeper in color, sp. gr. 1020, reaction acid, faint cloud on heat, and nitric acid. (8 r.m.) Mr. Stephens, of Hoddesden, and Dr. Habershon, joined me in consultation. We considered the symptoms due to intusensception, though no cause could be accertained beyond a subden change to a more luxurious and mixed diet than the child was accustomed to at home. Restlessness and refusal of the bowels to act (notwithstanding the temedies tried) were the chief symptoms. Three grains of the biturbenate of soda were added to each dow of the mixture. Four ounces of urine drawn off. A copious warm scap and water enema was thrown into the rectum, and three or four small sorbale came away, which could not be detected in the morning. Dr. Haberahou thought the belladonsa had brought them down. He considered that a postion of the ileum had slipped into the cacera; but my first hopeassion was, from the twisting umbilical rais, and the absence of any lump or delness in either illusregion, that the displacement (if any really existed) took place letween the lower portion of the jojunum and the upper part of the beam. The paralysis of the bladder must have arisen from ay supathetic irritation.

Sth (10 A.M.) .- No action of the howels or sickness; has passed a little prine. At the upper constricted part of the rectum lift sucro-ilize symphysis) I felt something hard protrailing through it for about an inch, and between the rectum and bladder at its upper part was an elastic fulness, which I considered to be a distended convolution of small intestine. An O'Beirne's tube, well niled, was passed up gradually into the descending color without mosting with any resistance. An enema of sixteen omsess of warm soop and water, with two ounces of infusion of rhubark, was then inhoted, and it speedily returned as thrown up. Shortly after this, a repetition of the enema brought down a mass of femilest natier four inches in length; and by continuing to wash out the rectum, the fulness much diminished behind the bladder. A warm positice was applied to the abdomen, and the belladenna mixture continued, (10 p.m.) No further action of the lowels; rectum empty.

9th. In measy sleep, waking up at intervals in pain and discomfort; the tympanites was less over the stomach, and the margins of the ribs could be distinctly seen over the hypothesdria; jule referred to hypogastrium, but no tumor could be felt; has passed a little urine; injection repeated, followed by the escape." of a few small scylule. Puly, Ipecac, Co. gr. iss. to be given every four hours, if in pain,

10th.-A few scribalous masses came away after an injection of marm water.

lith.-Rectum empty. Half an onnce of warm lineed oil thrown into the rectum. Has passed water three times succe yesterday.

12th.—During the latter part of yesterday there were three scanly actions of the howels, with considerable pain for three or four hours. Twelve cances of warm scap and water were injected, which returned antinged with forces. An ounce of warm inseed oil was therefore thrown into the howel.

15th.—The abdomen was more tympanitie, and painful at the lower part. She passed water freely, and there was tenesions, but no motion; pulse 112, weak and thready. I thought this increase of pain and swelling might be owing to the bowel, after recovery from the invagination, again slipping down into its old position. A few drops of brandy ordered in a little thin arrowned every three boars.

14th —A very slight cozing of feeal matter.
15th.—Bowels moved slightly three times.

16th —From 10.32 till 12.30 has night she was most oncomfortable, after which she passed a dark-green liquid motion. At 2 a.m., one copious has less dark motion, at 3 a.m., one of a brightyellow color, all being attended with pain of a griping twisting character; at 11 a.m. there was a rather lunger action of the bowsis; at 8.30, 11.30, and 12 r.m. a liquid motion, so that it was evident from the quantity that had pessed, there must have been assumulation beyond the immediate reach of enemata.

17th.—A soft motion was passed this morning, when the child shricked out with more pain than she had felt before, and clasped her mother; the pain was referred to the umbilious, but only a slight degree of tympanites could be detected in this situation. Though this escape of focal matter might have been sufficient to irritate the bowels and produce pain, it was possible that a portion of intestine had become invaginated or twisted from time to time, or the pain was due to the howels being thrown into commention, causing irregular contraction or spane, by their free action. Two grains of the Pulv. Ipseac. Co., and the sixth of a grain of calonel, were ordered every two hours if in pain.

18th.—Had seven hours' sleep. Took two powders.

19th.-Bowels open four times.

20th.-Bowels noted twice-a good night.

21st —Bourds moved twice. Went to her home in the country.

April 10th.—Mr. Stephens reported that the journey home threw
the shild back a month, and ensumts were required every third
day, in order to set on the bowels. There were tenderness and

tympanites, and only small scribbless motions were evaruated. For a long time after her return home the temporal force were greatly annken, and the skin was like vellum from the absorption of fat.

January, 1876.—For some three months past the child had been quite well.

In this case the degree of constriction was too slight to entirely prevent the passage of the intestinal contents, and the chief danger lay in death from exhaustion rather than from obstruction. The normal vermicular movement of the intestines in these slight cases has the effect of restoring the invaginated gut to its proper place, when rost and appropriate measures are adopted.

The second entriety of interests option is that which chiefly concome us, by producing very positive and unistakable symptoms, in addition, in some cases, to a defined abdominial tumor, and the partial protrasion of the invaginated intestine (sausage-like in shape) into the rectum, within reach of the surgeon's finger.

A mass of cougula may be mistaken for an intususception, as in a case recorded by Mr. Morris, in the twenty-eighth volume of the Poll. Soc. Trans., where an intususception of the Benn astually existed, but this did not involve the large intestine, which was full of closs.

In genuine intessusception, it is the upper segment of the level that is almost invariably forced into the lower. Brinton doubted whether the contrary can ever occur. Ascending intresusception," however, is apoken of by some writers,! Handfield Jones and Herbert Page describe a case whore both varieties occuisted, and "the extremities of the two intessusceptions overlapped each other."

The proportion of frequency with respect to age goes to show, that of twelve specimens in children noted in the Museum of the College of Surgeons, two were aged respectively four years, one a year old, and none of the remainder exceeded ten months.

The proportions of frequency in the different parts of the came

[&]quot;In the Massum of the Follogs of Stageons is a speciator of a cur's investing with an according of retrigends infrastrupption close to one of the cellinary variety.

⁵ Melos and Popper, p. 463.

² A Card of Intrastrumption in which Abdominial Section was performed, Moll-Chir. Trans., vol. lai.

which are liable to this displacement are as follows, according to Brinton:

House and excuse into large intestine, 56 per cent.

"Half the large class of ilso-crecal intussus-eptions are infants under seven years of age, many but a few months old."

"Small intestine invaginated into a lower part of small intes-

tine, 32 per cent."

Colon intossuscepted into itself, 12 per cent. (Assorbing to Rekitmasky, however, "Introsusceptions occur with equal fraquency in the rolon and small intestine.")

"The rectum scarcely ever forms more than the outer layer of

an intrasperention which has descended into it from above."

Brinton believes that the elonghing-off of an intrasusception is not complete ou an average before the eighth day, and the liber ated bowel is not expelled till two days inter; "and as the intrasusception, where primarily fatal, mostly kills in about five days and a half, we may fairly conjecture that the custing loose of the invagination is sometimes only prevented by the death of the patient" (Brinton.)

The average duration of the cases directly fatal, appears to be the same in the different varieties, five days and a half.

Antionical Approximes.—There are numerous specimens of inturnesception at the Museum of the College of Surgeons, showing the direction which the displaced intestine takes. In nearly all cases from the human subject, it is of the descending variety, or in a direction downwards,

In infants, the lower end of the ileum suffers most frequently.

This is owing partly to the losseness of the attachment of the
cocum in the right iline fossa, and the imperfect development of
its muscular cout in early life, which allows the ileum to slip
through the valve.

Course.—Intussusception in very young children may arise from many disorders of the alimentary canal, especially diarrhest; indeal, this is a common cause in infants; even in older shildren, diarrhest, mano enteritis, and dysenteric discharges are capable of originating the complaint. In a large number of cases it cannot be denied that demangement of the functions of the intestinal viscous precedes the displacement, and since it happens so fre-

^{*} Intestral Observation, by Win. Briston, M.D., F.R.S., edited by T. Barrard, M.D.

quently to young children, it may be accepted as a certainty, that broughlar contraction of these viscora from the ingesta is a commucause of the disorder. "The cause of this absormal involution appears to be emblon and spasmodic contraction of a pertion of intestine, impelled ouwards into a portion less contracted or altogether flaceful. It occurs at all periods of life, but perhaps is more frequent in youth and infancy."

Of 52 cases tabulated by Dr Lewis Smith, the health was recorded before the invagination in 34; of these 34, the previous health was good in 17, and deranged in 17; the previous health in most of the 17 consisted of diarrhous or dysentery, or diarrhous alternating with constitution; others had threadworms, obscure abdominal pains, names, and veniting. One shild had symptoms

of invagination at ten receive old, which passed off ?

The male sex is most liable to the complaint, and of 54 cases, 23 were boys. (Lewis Smith.)

The liability of young children to the disorder is in a great measure due to the delicate structure of the walls of the intestine, which are imperfectly developed in infancy, and to unsteadiness in their movements.

It is not proved that intrasusception is due to congenital laxity of the mesoscenta or mesoscion.

Among the exciting causes, blows and continions of the ablemen have produced discribes and constitution, followed by invagination; violent fits of screaming, and straining at steel have induced the complaint. Tossing the child-up in the arms anddenly with a jork, and then bringing it quickly to the ground, may cause intrasusception. (Rilliet and Barther.)

The simple form of intusueseption is usually situated in the small intestines, and very rarely in the colon; in the more aggratated form the illum is generally invaginated into the colon. The latter is, as Brinton has shown, the most frequent.

The howels may not as many as four or five times a day, and the child die not withstanding, and after death the invaginated intertine may be from one to two feet long. The bowels may remain pervious for weeks, and then death ensur.

Symptoms.—These wary in severity according to the age of the child and the cause which may have produced it, but griping pas-

^{*} Haberthon, op. cit;; p. 318.

[†] Lewis Smith, op. siz., 1969, p. 420.

exystial pain, paller, faintness, and constitution, are common in most cases, increasing after a low days when enteritis is established. At first, as in the case of simple invagination related, presence is borne by the fand, and the little patient may have comfortable soutches of sleep; but if the invagination continues, the aemptoma assumo a more aggravated form, and inflammation, marked by great abdominal pain, voniting, and tenesmus, arises in the displaced portion of intention. If the child is very young, contribions may supervene," and even if this complication does not arise, the child soon loss flesh, the face is pinched and haggard, and the eyes dark and sunken. Ventiting is a frequent sympton, and cases are rare where it is not present; at first the contents of the stomach are simply rejected, and afterwards the ejecta are grass-green, and ultimately become stercoraccous, as in the well-known romiting in cases of strangulated hernin. After a day or two, the howels generally cease to act, and a few more sunty eracuntions will not in these cases prove that the lowels are not obstructed, for the excrementitions matters may issue from below the ear of obstruction. These scanly motions are generally tinged with Mostl, including much muons, and are very characteristic. But as Mr. Marsh has pithly remarked in regard to the case of a joing child in his own experience, r intuses coption, even though it involves a considerable length of intestine, does not necessarily produce any symptoms beyond those that commonly attend slight cutarrhal enteritis. The development of symptoms depends open the degree of constriction. In this respect an intessusception is like a heroin, which may be 'down' without being strangulated or even obstructed. And to say that vomiting, constitution, and the discharge of blood and mucus or scrum from the bowel are the samptons of invagination is inexact, in the same sense, in which it would be to say that vomiting and constitution are symptoms of bernin."

A solid cylindrical tumor may generally be detected by careful examination. It is most frequently found in the right ilia; or hypogastric regions, sometimes it can be felt by passing the forger

[•] The Habershon records a case of intraspectation where convolution and impactibility followed constitution, vanishing, and pain in the abdomers, in a key six years of age. Notwithstanding that he possed the cucum, together with the remaining passess and according exists, in a making, he completely recovered = Op. cit., p. 227.

f A Unio in which Abdissional Section two performed for Internaception, St. Barth. Blue, Ber., vol. xii.

up the rectum, but it may be obscured by tymponites due to the enteritis which it produces. When it can no longer to diens, guished after having once been detected, it may have shifted, but more frequently it has slonghed off.

Diagnosis. - In endeavoring to form a right conclusion as to the cause of the symptoms of obstruction, we must not hastily infer that they arise from intussusception. "I admitted into St. George's Hospital, some years ago, a little child who had many of the symptoms of infussusception, -olatinate constitution, straining to go to stool, occasional vomiting, and, it was said, a bloody discharge from the awas occasionally; and in whom there was also to be felt a kind of oblong tumor, somewhat tender to the touch, at one part of the abdonson. All this rather pointed to introom. orption, but the course of the disease convinced me that the carof the obstruction was really (as I believe it very often is) limited peritonitis, producing adhesion or impaction of neighboring colls of intestine."4 It may be impossible to distinguish the vomiting, feeble pulse, tynganites, and worn look from local enteritis or internal strangulation, but when mucus and blood are passed per aroun, it greatly assists the diagnosis. "The sudden caset of the yoin, and its subsidence, becoming aggravated in paroxysms, is an indication of this form of obstruction." The symptoms often commence insidiously, and are so puzzling that the ripost judgment may be deceived. It may be mistaken for enteritis, but the history should come to our assistance, the temperature and febrile excitement are not so great, and the colleky pain is more paracyamal and severe. "In contrast to simple colic the spasm is more regular in its recurrence, there is less sensation of twisting and grinding, and more of a continued paroxysm, caused by the violent and energetic action of the muscular fiber to overcome the abstruction; the large coils of intestine may sometimes be felt relity and turning over in the abdomen during its continuance.";

"The novements and throse of intestinal obstruction, afiled to the pain and intense constitutional reaction of cateritis, form, in the carrier stages of intresucception, a concurrence of symptoms so characteristic of this state as often hardly to require the decetion of the swelling produced by the invaginated bowel." (Brinten)

¹ Helmo's Surgical Tremmon of Children's Discuss, 1965, p. 563.

[†] Habershot, up. vit., j. 258.

Medical Binguesia, by Dr. Barelay, 1939, p. 490.

Let it also be borne in mind that in forming a diagnosis we should received that hardenest and impacted fierces, typhilitis, homorrhage, dysentery, peritonitis, and choicen infantum may all be mistaken for the condition we are describing; and that the symptoms belonging to each of these states must be carefully observed and compared, for the diagnosis is not unartended with difficulty.

When the obstruction is high up in the intestinal tube the urinary secretion is more scanty than when it is situated lower down; but this symptom names be much relied on. "Still less reliance is to be placed on the allegation that comiting comes on carrier, and is more distressing when the obstruction is high up, We incline to believe the cause of the obstruction to be invagination if a little bloody muchs be passed by stool, if a aniden pain were felt before comiting had been experienced, and when constipation had not been known to exist."

Intrasusception may end fatally in a few days, or terminate in recovery in three weeks. In infants the discuss is almost invariably fatal.

Intusansorption of the small intestine is readily distinguished from the ileo excal and colic forms.

Finall intestine alone involved.

- L Little or he lessession.
- 2 Much handwhage by stool and conit-
- I Symptoms of electraction very cody.
- 6. Tomor small and marcable,
- A foreignation jed 6dl per rectam.

Excepted formand cope form.

- I. Mark between
- 2 Shaple Mush-triting of actions,
- 2. Observation late or about.
- 4. Tunice large, more firml, may to feel,
- 5. Invagination of endetected per redom.

Sloughing and expulsion of the intresusception is most frequent when the small intestine alone is involved. Recovery too is tar more frequent in that variety than in ileo second or colic intresusceptions.

Frontsent. — This is suction, such and, and operative. The symptoms in many cases at the coset are too obscure to indicate with anything approaching certainty the lesion we have to escenter. Mucous discharges from the board, romiting, tenesmus, and the escape of blood are not conclusive signs. Even distribute and intestinal decangement, which more properly belong to an irritated rather than to a displaced intestine, may be present in cases of intrespectation.

Whenever symptoms of obstruction of the bowels present themsolves in a young child, we should not overlook the possibility of intusousception. When the seizure is undden, and displacement is considered no longer doubtful, we may adopt remedies with some chance of success. If there be a tumor in the abdomen with localized tenderness, two or three broches may be applied over the spot.

If there be no sickness at the beginning, and constipation be the chief feature of the complaint, a dose of caster oil may be necessary, and warm-water encusts; but if these should fail to nave the bowels it is no longer advisable to continue them, but to substitute in their places remedies of a soothing and sulative character. The intestines may be kept at rest by opins in small and repeated doses, and femoutations to the absonous may be used, or a warm bath. The opins will often allay the distressing sickness which is present, and iced water, ice to suck, or hydrocyanic ask will all be useful. Sometimes a small mustard positive to the pit of the stomach will stop the sickness.

The chief aim of the stofical treatment assists in the most absolute repose and the simplest diet, that the intestines may be kept face from commettion, and bulky matters, the refuse of digetion, may not enter them. Under this plan the bowels have, after many days, often gradually righted themselves.

The ecolorison treatment consists in the forcible injection of enpious encounts of warm water, some and water, or thin grad. This simple measure is often successful, for where the intramaception takes place between the ileum and excum (as it frequently does), the fluid may pass beyond the valve into the ileum, and overcome the resistance. Another plan is to pour warm water through a funnel at a varying height, according to the force required. A piece of india-rubber tubing, about two yards long, is attacked by one extremity to the funnel, and by the other to a tube, which is inserted into the rectum. I have recorded a very interesting case, successfully treated in this manner.

Inflation by means of air has been used unecessfully since the time of Hippocrates, and it is doubtful whether, in these modern times, it is practiced as often as it ought to be; for when it has

^{*} Intestinal Obstruction in a Child: Tremment by Reliadrens and Gradual Injection of Water Water proceed into the Section through a Forest and India-rather Ining, Encovery. By W. H. Duy, M.D., Ben. Med. Jones, May 31st, 1979.

been employed in children, many cases are recorded where the resistance has been overcome. A pair of ordinary bellows may be used, the nozzle introduced into the rectum, and the inflation proceeded with till the obstruction yields.

The augical treatment consists in performing the operation of gastrotomy, when all other measures have proved unavailing. The cirrumstances of each particular case must be carefully weighed—the urgency of the symptoms, and the strength of the patient; the probability of inflamounties, and the prospect of alighting on the seat of mischief. From what we have learned of late years respecting the tolerance of the peritonoun to local injury, and with what impunity it may be hardled without exciting inflamountion, there is reason to think that the lives of many children might have been saved if the operation had not been too long delayed.

Many writers, however, are of opinion that this treatment is attended with too much risk to justify the step, because there is difficulty in ascertaining the seat of obstruction, and even if found, the operation is attended with extreme danger. If a tumor can be felt in the left iliac fosse, where the interse emption frequently is located, there is a fair chance of localizing the constriction, and the operator has not to search at all parts of the intestinal tube. Besides, the distance to which essential travel may aid the diagnosis. It seems certain that if the operation holds out any chance of success, it should not be delayed over three or four days when the symptoms are severe; because the invaginated borrel may inflame and contract adhesions with the succonding parts. "Only three cases collected by Havon, in which gastrotomy was performed, terminated favorably."

The two following are examples of gustrotomy, one fatal, and one mecessful.

Case 1.—Mr. Hutchinson has described an interesting case of a thild six months old on whom he operated. The child was under the care of Dr. Madge, and had been in four days when he saw it, with painful straining and the passage of bloody mucus. "The invaginated part could be easily felt in the left flank by manipulation through the abdominal wall, and also by the finger introduced into the rectum." (An infant sister died a year previously of the same lesion.) The intraspection had begun in the execut, and at the post-mortem next day there was universal peritonitis, and

[&]quot;Meigs and Pepper, op-rit . js. 677-

the execute was attached by a long moventery. Mr. Hutchinson, considered that the assume had been loner congenitally,"

Case 2-Mr. Howard Marsh! has described an intensting not uncessful case of gustrotomy. The child in male infant seven months old) was seized, fourteen days lafore he saw him, with diarrhosa, sickness, and occasional griping paint in the abdomen. The case was considered by the medical attendants, Dr. Miller and Dr. Barnes, of Eve, in Suffolk, to be due to catarrhal enteritie. and natural emenations followed small deses of castor oil englsion. In two or three days griping and stekness returned, and there were in addition tenesmus and a quantity of slimy macus neixed with blood. The child remained in much the same cools. tion till twelve hours before the consultation (April 11th, 1875). when the pain and tensemus were violent, and he became pale and restless. On examination a firm cylindrical and sansage-slaped tumor was felt in the abdomon, "extending from the umbilious to the left line fossa," and two inches of the bowel protrudel from the anns, with the ilencercal valve at the extremity. Insufflation and warm-water encounts failed to reduce the invagination. The child was placed under chloreform, and the abdomen having been opened, the entering portion of the gut was carefully pulled out, when it was found that the invaginated intestine "included at least half the colon, and an equal portion of the small intestine." After the operation small doses of hudarum were given, and the child drank freely of nelk and water. The sirkness consed at on e. and two days after the operation a formlest motion was passed. The wound had nearly healed eightyfour hours after the operation, and a few days later the child resovered. Nine months after the child was in good bealth. This case is one which testifies to the importance of an operation when the symptoms are severe; and shows that the possibility of strangulation or inflamouation being present, should not prevent the operation, when the case holds out no other hope of success. In rases which appear most formidable before the operation, the invagination having been restored, improvement may at once set in, proving that the circulation through the bowel has not been interfered with.

CHAPTER XX.

DESTABLE OF THE LIVER.

Testamentos os sus Lives. Meterro-Symposis and fromest. Atentation less americas os sus Lives. Histories—International Reporter House America. Symposis—Const.-Principal -- Model and application. Symposis Decease of the Lives—Americanous Explorations.

Commerces of the liver is not unfrequent in children. It is manifested by constipated bowels and clay-colored evacuations; the appetite is poor, the complexion sallow, and the tengue coated; the conjunctive have a yellowish tint, and the nrine is highcolored and turbid on standing. There is a sense of weight and folioss about the region of the liver, and its edge may sometimes be felt below the ribs on the right side. This is a state of order congestion.

It should be remarked that in making an examination of the liver we shall find it proportionately larger in early life than in adult life, and that what would be considered as enlarged area of hepatic dubiess in the latter would not measurably be so in the former.

"In the adult the average weight of the liver is one-fortieth that of the entire body, whereas previous to pulserry it may be as much as one-thirtieth or even one-twentieth." The liver varies in health as to size, and there is more blood in it at one time than at another. "For instance, the amount of blood in the liver and its size are greatly influenced by diet, both being temperarily increased after a meal, and particularly when the food has been too large in quantity, or has contained an excess of fatty, suc-barine, or alcoholic ingredients."

The pathology or nature of the change consists in a uniform sulargement of the liver, which is also darker in color, from containing more blood than it does normally. The congestion may affect chiefly the hepatic or portal vein; the lobules have in the first case a light border, and in the second a dark border. The congestion, therefore, is specien of as intralobular and interiobular.

The owner are overfeeding and inattention to the rules of

Lessures on Dissume of the Liver, by Dr. Murchison, 1377, p. 7.

[†] Thist, je Life.

health. Bish and stimulating foul in large quantities, especially if children are confined indoors, and do not get sufficient evereise; or cold after a heavy meal may induce it. Organic disease of the valves of the heart, as mitral regungitation, and more or less distension of the right cavities, will, by inducing a mechanic cal obstacle to the return of bood through the veins, set up prosing congestion. Under these streamstances the liver is liabitually congested, and it grows larger, at least for a time "The pressure exerted by the constantly distended hepatic volus causes atrophy of the central poetions of the lobules, and induess a form of granular liver, different from true cirrlesis, where the atrophy commences at the circumference of the lobules." An enlarged liver may sometimes occur in connection with chronic discount the lungs. In two cases of emphysiona of the lungs, in children under my care, the liver was calarged in both ; it may be present in ascites, and concetines produces it; it occurs in meandain disease, and in rickety subjects, where the head is large, the torth decayed, and the limbs small.

The symptoms are a dragging pain or tightness below the right ribs, but, as some children will bear pressure ofthout complaining, the physical signs denoting colorgement of the liver are mostly to be relied on for diagnosis. In a large number of cases pain is altogether absent. There is now and then some degree of jamdice present, but this is more often seen in adults than in shildren; the liver may be felt an inch below the rile, and the motions may he deficient in hile when the skin in perfectly clear. Simple congestion of the liver, therefore, in children is not usually actorded with jambles. The prine is scanty, and on standing may throw down copious grates, though it is sometimes perfectly clear and natural. The general signs are headache, nausen, loss of appetite, farred tongue, fatalence, and even vomiting. There may be diarrhesa and irritation of the bowels, languer and Mrowelters. The liver may remain large after jaundice for a long time, and pain of a dragging character caste, with despeptic symptoms, headards, and basitude. As the circulation is relieved and the turgid capillaries are unloaded, the jaundiced bur, which is not necessarily present, passes off.

Trestand.—We must first aim at the removal of the cause. When congestion of the liver happens to young children from

[&]quot; Lectures on Discours of the Liver, by Br. Moredison, 1877, p. 112.

overfeeding and inattention to the rales of health, care and attention to dist will soon cure the compaint. In the shape of medicite a mild norcurial, followed by a saline apericut, will existe a watery discharge from the minimus monditions of the bowels, and bring away some hillions methods. A warm bath at bedtime for a few nights is an admirable remedy, and if there is pulse or weight. over the region of the liver, a but poulties will be henefold. The perchloride of mercary with tinctany of bark is often useful, and the nitrohydrochlorio neld and taraxnoun (Form, 42) where there is debility and dislike to food. When the congestion is due to disease of the thoracle viscora an occasional calomel purge, followed by a suffine aperious in equally available, and the dist will require to be regulated. A small dose of calonel stimulates the upper bowel and doedenum, and drives the bile along the intestimes. Small doses of iperacumulas are also useful by increasing the action of the liver and skin.

When children are sleepless and irritable, bromake of potassiums is useful if the liver is congested, and the urion high-colored and scanty. In similar cases, the chloride of ammonium, which acts on the skin and kidneys, is an excellent remody, though rather too reassons for children.

Later on, when the urine is clear, and there is debility, the symp of the lodido of iron, nux romios, or arcenio, are suitable remedies.

Adhrair Liferancetion of the Liver.—The liver may be enlarged from interstitial hepatitis or adhesive inflammation, and attain a large size, stretching above to the aippir, and below to the navel. In an early stage it has been known to extend to the pubes, and the spleen to be enlarged at the same time.

In cirrhosis the liver is at first increased in size in consequence of an infiltration of small round cells into the arcolar tissue of the portal canals, and the increase of the organ depends upon the extent of the cell proliferation. After a time, as this cellular tissue fibrillates and contracts, the liver diminishes in size the pertal reins are compressed, and the passage of blood is impeded; the rescularity of the liver is lessened, indeed some of the branches of the portal vein are entirely obliterated, hence strophy and shrinking of portions of the liver. The small gall-ducts undergo compression in the same way as the branches of the portal vein. Wilks and Moxon consider that in many cases there is no proof of

lymph being thrown out as in active inflammation, and that the whole change is chronic."

An interesting case of circhosis in a child is recorded by Dr. Arthur Fox, i accompanied with jaundice, humateuseis, and coma, After death the liver was found unusually large, the capsule thickened, and the surface finely granular. "The glauds in the portal flooter were much enlarged and despity pigmented. The apien was encreasedly garged with blood and somewhat friable." The kidneys were congested but otherwise normal. The intense jamadice was attributed to the pressure of the enlarged glands on the bile-duct. There was no history of hereditary syphilis, but his mother had been a chronic drinker for years. Dr. Fox comiders that circlesis in children may be one of the consequences of alsoholic heredity, though it may occur independent of it as a grave general discoses.

The Murchison relates a case of interstitial hepatitis in a shill twelve years of age, coming on from a chill, and ending in cirriotic contraction and death. The discuss set in slowly, followed by severe abdomized pain and deep jaundice. The liver extended nearly to the pulses, and the spicen was calarged. Death was preceded by discrines, with hemorrhage, offensive breath, mpid pulse, fever, delirions, irregular breathing, and come. A postmorrous examination revealed a small rounded fiver (bloomes), the tissue being firm and the surface irregular and packered; capsule thickness; spless enlarged \$\frac{1}{2}\$

Conser.—Spirit drinking is the ower common rause of sirrhuis in the adult. When taken up by the bloodvessels of the stemach, alcohol is at once conveyed to the liver. Murchison relates a case in a boy, nine years of age, who drank "a good deal of wine and water between meals." Paracestesis was twice performed. He died from prestration and collapse. After death the liver was found tough and holomiled, and weighed 214 ourses. A treple and sluggish liver, bereditary syphilis, cold and chills, and the want of regular exercise have given rise to the discuss in children.

According to Dr. Budd, the small miliary tubercles found to

^{*} Pathological Assessay, 2875, p. 542,

^{2 &}quot;Case of circlesis in a boy aged above spars; jumilies of nearly then your boundary." — Not. Med. Josep., Dec. 21st, 1878, p. 918.

^{\$} Lecture on Discuss of the Liver, by Dr. Marchison, 1877, p. 682.

Op. cit., p. Dic.

the liver of persons dying of phthisis never cause adhesive inflammation of the organ, which, as he says, is remarkable, seeing the tendency they have to set up inflammation in the different rissues of the lung."

Dispersia.—This is not very easy in children who exceptionally indulge in alsohol. A sallow has of the skin, or even joundies; thirst, dry tengue, furred or reddish; senary and high-colored urine; costive lowels, with a deficiency of hile in the motions; pain in the hepatic region, and tenderness on pressure are to be looked for. Ascites is often present to a considerable degree. There is sometimes epistaxis, or homographe from the lowels.

Morbid Anatony.—The liver is much reduced in size, and of a yellowish color, resembling becomes. Fibrous tissue of a tough character is diffused through the organ and around the vescele. As it contracts, the parenchyma is squessed into a course redular appearance; the capsule is thickened; the walls of the portal vein are also thickened, and its collibre is diminished. The hepatic cells are destroyed, or in a state of fatty degeneration.

Freeheart.—Diet is important. It should consist of milk, eggs, white fish, farinaceous food, and positry. At an early stage, when the liver is congested and tender, the application of two or three breches may be accessary, or a linear positive frequently renewed. Small doses of hyd, c. creta with chalarb are serviceable, and a saline aperient to unload the portal circulation, and keep the bourle freely open, will relieve the symptoms greatly. If there is less of appetite the compound infusion of gentian, taraxacum, and dilute nitric seid may be given. When anties threatens, distreties, such as the aretate of potash in decortion of broom, should be tried, and if they fail, hydragogue pargatives, as the compound judap powder, are indicated. When ascites is present to a degree which embarrasses the respiration and causes pain, recourse must be had to paracentosis. If there is a syphilitic history, increary and loaded of potassium may be demanded.

Syphilite discuss of the least is another form of hepatic subargament. The beions of this organ seen in hereditary syphilis usually consist in hardening and hypertrophy, so that it creaks as the knife passes through it. "On a uniform yellowish ground a more or less close layer of small white opaque grains is seen, having the appearance of grains of semela, with some delicate arborescences formed of empty blo dvessels. On pressure no blood is forced out, but only a slightly yellow serum, which is derived from the afterner." The change may be limited to the right or the left ble of the liver. The capillary vessels are obliterated, and the dimensions of the larger vessels reduced. The microscope shows the morbid appearances to be due to the presence of a fibra-plastic material. These changes may be developed during interacting life. The symptoms are not very definite; there may be constring, disrebon, or constitution, but never any jaundice. Buth takes place early. Fatal peritonidis, it has been said, may be the consequence of the hepatitis being followed by the extension of infamonation from the parisonnal covering of the liver.

There is a case recorded by Dr. Goodbart, r in which the liver and spleen were very large in an infant two months old. The oridense of congenital syphilis was doubtful, but a core was effected by one grain of gray powder, given night and morning, followed by the syrup of the isolide of iron.

Frerichs speaks of three forms of syphilitic disease of the liver:

1. Simple interstitial hepatitis; 2. Repatitis gummesa; 3. Waxy, amyloid or landacous degeneration of the liver. All three forms may be found in the same liver, or may exist independently.

There is alternated enlargement of the liver, in which alternaons uniter is infiltrated through the organ. It is commonly not with in rickety children. The organ is paler, harder, and more elastic than natural, and the connective tissue around the portal vessels is increased. A similar state of the liver is found in congenital syphilis. (Wilks and Moxon.)

CHAPTER XXL

POTERUS OR JAUNDICE.

Districts Ann Statement Prince Cold and but atmosphere. The enterior of his on the blad from the monitor of the following and recovering of the natural but and resource of the natural but and resource of the natural but and resource of the natural but and the natura

By the term jaundice we understand a yellowish color of the integument, caused by the entrance of bile into the blood; this, with yellow conjunctive and urine, and the whitish or pipeclay appearance of the frees, distinguish it from every other disease.

The spentance of jamulies in children often commence with sickness and vomiting of food; there may be severe frontal bendache, larguer, and lassitude; the child can make no exertion to do augthing; there is loss of appetite, and sometimes pain over the region of the liver, though this may be absent even when the organ is considerably enlarged. Pain, indeed, is a rare symptom in the jamulies of children, and when present in the jamulies of adults, it probably indicates distension of the bile-ducts from the passage of a gall-stone. The surface of the body and conjunctive generally assume a yellow appearance, and the extremities are sometimes much more affected than the back. The temperature is normal, and the pulse slow, except there is neute pain over the fiver from the amount of congestion present, and then there is dryness of the skin and febrile disturbance.

The orine is generally of a dark Madeira color, from the admixture of hile, and it stains lines yellow. Casts of the uritary talmies have been observed in it. In very severe cases the sweat and saliva are also yellow, and objects appear yellow to the eye. The lowels are usually constipated, and the motions pale like piperity. Sometimes there is diarrhox, and the stools are colorless, if the blie-duct is completely obstructed. In cases where the constitution is had, petechine may appear on the skin, and there may even be been orthoge from the mucous surfaces. According to Wickham Logg, the tint of joundice has been observed by several authorities in the mouth before it has been apparent elsewhere.

Consex.-Jaundice results in infants and very young children

from a bad atmosphere and rold, so that the skin and organs of respiration do not perfectly perform their functions. The disease is most common in the feeble and delicate. As the skin takes on its proper functions, and cold is guarded against, the jamilies disappears in a few days, provided nothing is given in the shape of food except breast-milk. A grain of Hyd, a Creta, followed by a dose of castor oil or some other laxative, complete the treatment.

Jaundice may, however, arise from enlargement and inflammation of the liver or untillical veins, or from obstruction or inflanmation of the bile-ducts, or even absence of the gall-bladder. It has been attributed to spasmodic closure of the ducts, but whether this can produce it or not, we know that the essential or true cause is a retention of the bile within the liver, and the transnlation of the bije through the capablaries and bile-ducts into the circulating blood. Jupuslice may arise from congestion of the liver; the secretion of bile is diminished because the gorged state of the bloodyessels presses upon the gall duets, and does not allow the hile to pass freely through them. "In roomy persons, and in persome in whom the liver is healthy and its capsule thin, it will necessarily onlarge much more for a given force of distension than in persons in opposite circumstances." The liver is enlarged and of a deep-red color in the central parts, whilst the margins are pale.

Jaunalice in obter children, as in adults, is most common in summer and autumn, and in some cases is accompanied with diarches. Nausen and sickness, headache, loss of appetite, drowsinson, and restless nights are common symptoms. I attended a severe case of joundice in a young lad some years ago, which came on after excitement and running some distance innusdiately after a heavy meal.

Jamelice has arisen from round worms entering the critics of the bile-duct and causing biliary color, veniting, and all the symptoms of gall-atones.† A similar case is also on record.‡ Dr. Buddmentions the fact that several cases of jamelice, in quick succesion, have come to his knowledge in shildren of the same family, or in several persons living in the same locality. He attributes it to some poison (probably mission) which arrests the secretion of the

^{*} Tholdon the Liver, 1852, p. 56.

⁺ Mundison, op. cit., p. 54%.

¹ Teit. Med. Journ., vol. ii, 1878, p. 877.

liver owing to assue change in the blood.* Probably the liver was imperfectly developed. Some persons have small livers, just as others have small hearts.

The diagnosis from cerebral disease consists in the absence of felcile disturbance—no heat of head or intolerance of light—the coniting is less, and the pulse is slow rather than frequent. There is often tendersess over the region of the liver, the motions are pule, and the urine high-colored.

The treatment of journilies is that of biliney congection. If there is pain or great tenderness over the liver a looch or two may be applied thore or at the anns, followed by a warm lineed poulties, Two grains of Hyd. c. Creta, or even a grain of calonel should be given at bedtime to a child seven or eight years old, followed by sulphate of magnesia during the day, or the aircomuriatic acid nixture, with taraxacum (Form, 42). It is important to keep the bensels open and to give a farinamens diet chiefly. Milk in sodawater a nutritious and refreshing. If there is thirst, barley-water, with a little cream of tartar in it, will be useful. Bigarbonate of wila and tartaric acid given in full doses whilst efferresting will relieve stekness and keep up a gentle action of the bowels. If the liver remains aluggish and painful, a lotion of nitric acid applied at beltime under oiled silk is a good application. It causes relness and tingling of the skin, and when this happens it should be omitted till the crythema has passed away before it is reapplied,# Emetics repeated daily are in favor with some practitioners, especially when the inundice is due to catarrh of the bile-ducts.

After a recommend is not a discuss of the fiver, as its name seems to imply, but is merely caused by the changes in the color of the skin during the first few days of life. In infants after birth the skin is much congested; this gradually declines till a resy that is reached in the course of a few days. It sometimes happens in shildren otherwise well, that the skin, after the first two or three days of life, assumes a yellowish-crange tint, which popularly goes by the name of joundies, the urine and motions being in all respects natural. The complaint is caused by the blood in the skin

^{*} Discount of the Liver, 1853, p. 272.

[#] Freenals 44:

changing into a yellowish tint before the normal color is marked. The conjunctive in these cases remain clear, and the princ contains no trace of bile-pigment. The disorder is, therefore, in most cases, a more cataneous discoloration.

This simple form of interns has been shown to be frequently due to dedicient exygenation of the blood, but " decas reconstruct may also represent a very grave condition, viz., obstruction of the bits-duet" from congenital stricture, or from inspissated bits, or the hundles may have a pyemic origin from pholostic of the untilinal wein, as Dr. Murchison has shown (up. cit., p. 347).

A male infant, seven weeks old, was sent to me by Mr. Batter, of Guildford, on April 8th, 1879, suffering from severe launtice. On the third day after birth, he became very rollow, but took Swiss milk well, and was also suckled by a wet-marse. The child was well nourished, and had not wasted, though the mother said he seemed less plump than at birth. The color of the integument was of a deep yellow on the face and thorax, and of a lighter but below the umbilious, scretum, and butterks. The conjunctive presented a yellowlsh-green tint, varying from time to time in intensity. Both the liver and spleen were mlarged. There was a good deal of tympunites, but the child could retain his food; there was no comiting, the faces were relaxed, and although nearly always clay colored, a trace of bile had been seen in the mations; the urine was of a pule-suffron rolor. The history of the case favored the supposition that the jamslice might be caused by absence obstruction, or mulformation of the gall-leader to bileducts. He was ordered to be fed on milk and limewater, and as the diagnosis could at best be only doubtful, a powder containing a grain of Hydr, our Creta and bicarbonate of sola, was ordered, occasionally at bedtime, and a mixture containing the solution of carbonate of magnesia and turaxacum during the day.

Mr. Butler informed me, six months later, that the shill had died, and a post-morten examination had been made by Mr. Bisslaup, of Tunbridge Wells, on August 21d, 1879. A goodded

[&]quot;Me. Oblistes has showing a most appropriate one of facility across as a summary where the constants hills that was hard to be constructed, "a few than from its indexed interests," and the left hapatic dust "accound to aplit up into theses threads." The realist had been seven whileless inches, six of whose had shown similar symptoms, from out of these six cases ending facility. Both parents were troubled with frequent hepatic symptoms.—Lenist, vol. 1, 1979, pp. 253, 200.

of ascitic fluid was found in the abdominal cavity of a deep-yellow color, which appeared due, not to any inflammation of the peritoneum itself, but to the dense, hard, contracted state of the liver, from chronic inflammatory changes, which had obstructed the hepatic circulation precisely in the number seen in circhosis. The gall-bladder contained a glairy white fluid, but no bits. The hepatic cystic, and common bile-ducts were all absent. The anatonical malformation had caused the incurable jaundice, the chronic inflammation of the liver and dropsy, and finally the general wasting and death.

Acute yellow advapley of the lines (apparental accretion of lifefatal james (iv) has been met with in young subjects, but it is very rare in children. "Out of 25,700 cases admitted into the London Fever Hospital in nine years, there was only one case of this disease." It is supposed to consist in inflammation of the organ, which leads to suppression of tile, and degeneration of structure. In this curious disease the liver quickly undergoes degeneration, after a few days of indisposition, and heparic derangement. The premonitory symptoms are nausea, furred tongue, diarrhou, or constipution, slight pyrexia; there may be rheumatic pains and cardine distress. Jaundice is always present, but blie is to be seen in the stools, and there is no obstruction in the bile-ducks. The severe symptoms are owing to biliary suppression, and the accumulation of lake resolucts in the blood. The skin becomes bot and dry, the pulse quick, vomiting of coffee-grounds matters follows, with hemorrhage from the bowels. Sometimes there is epistaxis, and the borrels are constituted; the urine is of a dark-brown color, like porter, and contains bile, tyrosiu, lendiu, etc. As the disease proceeds, delirium and coma (sometimes convulsions) some on, the motions are dark from the presence of blood, the skin is of a deeper jaundice hase, and petechial spots of ecolognosis occur in different parts of the body.

In the case of a boy, aged screaters, described by the late Mr. Harry Leach, there had been "slight leterus for fourteen days, pain across the epigastrium, anorexia, and frequent veniting." These symptoms were followed by stuper, debility, intense jaundice, pain over the liver, which was enlarged, coffer grounds vomiting, convulsions, frantic delirium, loud screaming, and death. The pulse was weak and irregular, the respiration slow, the heart

^{*} Murchison, sp. cil., p. 257.

thumping. The bowels were constituted, the urine (which was
of the color of porter) required to be drawn off with a catheter. It
contained tyrosin, a large quantity of urea, phosphates, and chisrides, but no allumes. The sp. gr. was 1935. A post-morten
examination revealed congestion of both lungs; the speen weighed
4½ oz., both kidneys 10) oz., and were granular and farty; the
liver weighed 51½ oz —it was soft, pale, and flabby; the inferior
aspect was of a dark-greenish has from the accumulation of hile
in the independent portions. The biliary resides and due to were

This form of jamelies, ending in come, occurred to four measures of the same family; in the case of two of them, being brothers of the respective ages of 11 and 13 years, it terminated

fatallect

Course.—Syphilis, and Irregular liabits in youth, predispose to the disease. According to Frerichs, byperemia and diffuse inflammation of the liver are exciting causes.

Diagnosis.—The disease resembles yellow fever, but is to be distinguished from it by the shrinking of the liver, and the presence of lourin in the urine.

Mostof Ametong.—The fiver is shrunk and shrivelled, and the division into lobules is not discernible; it may shrink to our half its size in the course of a week or ten days, " it is not and flabby, and of a light-yellow solor, or brownish yellow, or orinson orange, or some blashed tint."

It may be unlarged at an early stage, but this is of short firms tion, and is seen followed by a diminution in its bulk. The hopatic cells disappear, leaving only granular matter and oil, the biliary duets are pervious, the gall-bindder is coupty, the splere is congested and enlarged.

Freehoust.—This is almost hopeless. At an early singe capping or leaching over the liver may be of service; an emetic, followed by a full dose of caloned, appear to be the remedies which in a few cases have been attended by recovery. Dr. Budd recommends sulphate and carbonate of magnesia, with small doses of salvolatile.

CHAPTER XXII.

PAINLESS ENLARGEMENTS OF THE LIVER.

HUNCTURE OF THE LATER. Publishy Supplies Court Dispute Translation and Translate. Languages on Advisor Dunian. Party Later. States. Reportments of Later.

Hypatro tumors of the liver, most common during the middle period of life, are rarely found in childhood or old age. I have seen a large hydatid cyst extending downwards to the umbilions, and across to the splenic region, in a girl eight years of age; and cases are recorded of its occurrence incluid reasonably pounger. A membranous sac or cyst forms in the liver, containing a colorless limped fluid like water. In the fluid a variable number of crats or bladders (accommonstance) are found, varying in size "from a millet-seed to a goose's egg." Hundreds or even thousands of these accommonstances are detected in a single parent cyst, to the walls of which the scotions of the echinococcus adhere. The sac or cyst is formed by the tissue of the liver, and is of variable thicktess, being thicker in tumors of old than of recent standing.

Hydatid tumors grow very slowly, and are generally painless, at least when of small size, and they are rarely accompanied by dropsy or jaunifes. This latter symptom will depend upon whether the common bile-duct undergoes compression from being surrounded by enlarged lymphatic glands, or is otherwise obstructed by some architect glands, or is otherwise obstructed by some architect jamphice. A case is also recorded by Dr. Cayley, in which a patient had repeated attacks of hepatic pain with jamphice. The hydatid came away per assum, and the health remained good.† Hydatid tumors may be large enough to fill the greater part of the abdominal cavity, or to reach upwards into the chest usurly to the cinvicle; they may not exceed the size of an orange, and when deeply scated they may escape observation altogether.

When they can be felt they are perfectly smooth, and they have an elastic or finetuating feel. Occasionally the so-called hydatid fromitus may be felt. If several systs exist, the surface of the here may be irregular or indulated.

^{*} Path. Trans., vol. 288, p. 156. Path. Soc., Oct. 20th, 1874.

² Disense of the Liver, by C. Muschines, M.D., 1977, p. 55.

Ascites is an occasional consequence of pressure and interference with the elsculation through the liver, but a case is on record where the portal fiscare was much pressed upon without producing this result." In some cases there is assemn of the lower limbs from pressure on the vens cava, and allowen has been detected in the write from the tumor compressing the renal vein. In very exceptional instances, according hydratid cysts have been found in the spleen and kidney.

Cours.—The adult temia techinomerus inhabits the intesties of the dog; the ova are voided in the feces of the animal, and being swallowed with the food and drink, find their may to the liver, lung, or some other organ, and there become encysted.

Disgussia.—When a tumor occupying the region of the liver is smooth and globular, and there is fluctuation with an absence of pain, fever, and jaunalice, and the general health moreover remains good, we should suspect the existence of echineses;. The possibility of absence or ovarian crest, and especially possible effusion, should be remembered, but these conditions could scarcely be rendounded with a hydatid cyst, if care to taken before coming to a conclusion.

Termination. - The contents of a hydatid tumor may ultimately dry up, and the sac become obliterated, or it may burst spentage onsly through the walls of the alslomen, or into the brooks, intestine, or streamch, and the patient recover. The east may suppurate and induce premia and gangrenous abscess of the liver, or it may burst into the pleura and produce fatal empoons. When it bursts into the lung, the patient spits up a hydatid from time to time, and as the disease proceeds and the orifice in the pulmonary tissue becomes larger, several by datids may be coughed up at one time. The symptoms attending this pulmonary conplication are frequent straining cough, constant experioration of a sangeineous or purnlent character, and a disgusting taste in the mouth from the admixture of bile. The most dangerous corse-quence is the liability of the sac under gradual growth and distension to alcerate and rupture into the peritoneum, and there we up fatal inflammation. The tumor, too, may continue to increase in size, causing such compression of the begatic structure, and

^{* (}tis. Trees, 1878.p. 236.

¹ Marchison, up. 126-123.

⁷ Bull, sp. cm, p. 444.

disturbing the functions of adjacent organs by its growth, till it were the child out by rain and exhaustion.

Treshord - Up to the present time, drugs have proved ussless, When the tumor is large, it should be tapped with a fine exploratory trocar, or aspirator, and the fluid drawn off. The withdrawal of a small quantity of fluid by the hypodermic syringe, as n neans of diagnosis, has been sometimes followed by complete atrophy of the syst. The cases most likely to still in care are those which have a thin cyst wall, and where the resides are few in number, or the arephalocyst is solitary. Several successful cases are related by Budd," and Dr. Murchisont gives a table of eighty cases in which a cure followed the operation of puncture. Morrover, inflammation and supporation may be set up in the use by puncture, and recovery even then may ensue; or the hydrtid may slowly exhaust the patient's strength, as we sometimes see in spening a large chronic absons. Even the simple process. of puncture is not free from dauger, as there is a risk of the irritating fluid escaping into the abdominal eavity and provoking inflammation. Several fatal cases are recorded from paneture, death occurring in a few hours, faintness, rigors, vomiting of bilious matter, pain in the abdomen, and crodness of the extremithis preceding death. Sometimes peritonitis has ensued, followed by a slow recovery ! A case is related by Mr. Beyant, where agenizing pain, lividity, unconscionsness, and sudden death folleved the tapping of a hydatid cost, and the result of the postmortens examination seemed to show that the portal voin had been transfixed by the trocar, and that the hydatid fluid, being sucked into it, acted as a fatal poison \$

Injections into the cyst have been tried, those containing in hime or carbolic acid being generally selected. Indide of potassium given internally, and indine ointment rubbed in over the enlarged hier, have severally been employed without success.

Landarous or amyfold discuss of the liter-scrafolous calaryenced of the liter (Budd)—is a discuss which belongs to the weak and rackectic. In this peculiar degeneration of the liver, waxy and fally matter is infiltrated throughout it, and in many instances a

^{*} Rudt, op. cit., p. 448.

¹ Marchison, Clinical Lectures on Diseases of the Liver, 1877, p. 77.

I Frericht on Discous of the Liter, New Syd, Soc., and ii, p. 251.

⁽ Clin. Tenne, 1878, p. 1288.

similar extension of the disorder can be traced into the different tissues, as the lymphatic glands, bloodvessels, sploen, and rend organs.

Pattology. - The liver is greatly enlarged and thickened; it may be somewhat paler than usual from a deficiency of blood, or at other times scarcely altered from its normal appearance. In some cases it presents a white appearance on section, and the lebules are either obliterated altogether, or they are scarcely to be distingaished. This "waxy" or alluminous matter never becomes hard, or shows any tendency to contract like lymph, which is the product of inflammation; it is destitute of cells or organization. The surface of the liver is smooth, white and glistening even when the disease is of long standing. "These circumstances," save Dr. Budd," "explain the fact that the foreign matter, though large in amount, does not much impede either the passage of the blood through the liver or the excaps of the bile through the duera." The locales become of a faint reddish color and enlarged, the gland structure is uniform and smooth, and on section resembles "smoked salmen." This peculiar deposit may occur is isolated portions of the liver, or it may be scattered throughout the estire organ. It is first deposited within the telcules, and between the secreting cells, which are diminished in number. A similar condition of the splasn often accompanies this degeneration. Microscopically oil-globales can be seen in abundance when the fatty matter is examined, but the great increase in the size of the liver is nating to the infiltration of this populiar morald matter stretching the enpoule and obliterating the appearance of the lobules. "It first affects the minute vessels, especially the arreries, and extends to the capillaries, afterwards invading the proper elements of the texture implicated." Syphilis and scrofnlous disease of the bones, especially when accompanied by chronic suppuration, are its usual casual relations. Caries of long standing appears to be a common cause. "Out of eighty-three cases of lanlaceous disease, we only-three were in connection with either suppuration or syphills, leaving but ten cases which were not esternish amounted for by these agents."

The governi symptoms are those indicative of anguan, gradual

¹ Diseases of Lover, 1852, p. 226.

² December on Lard moon Discuss, Path. Soc., Murch 18th, 1879.

wasting and exchexia. It comes on so slowly that if it were not for the increased size of the abdomen, so notice would be taken of it; there is occasional yellowishness of the conjunctive and a little tenderness over the liver. After a time there is languor and loss of appetite, gastro-intestinal derangement, and sometimes weniting and diarrhous, with pale stools. Forcer of an irregular type is common, attended with cough, dysprous, and quick pulse; the urine is often of low specific gravity from the presence of allemen, which is a consequence of the kidneys participating in the waxy degeneration, and the drain of albumen may be so great as to destroy life. The presence of waxy costs in the urine is a guide to diagnosis.

In addition to these symptoms we frequently meet with enlargement of the submaxillary and corvical glands. The disease may terminate in peritonitis, postmonia, or tubercular disease of the lungs; but more frequently it ends in exhaustion, ascites, or general anatoms.

In a case mentioned by Portal of a boy, aged 8, who died from the discuse, the bronchial and mescenteric glands were found enlarged, "and tilled with a substance like plaster," and a slice of the liver exposed to heat became bardened like albumen.* In another case, related by Abercrombic, of a boy, aged 11 years, there was found after death, extensive discuss of the mescenteric glands, the longs were tuberculous, and there was a clain of enlarged glands extending from the bifurcation of the traches to the displangen; some contained pas, others were of cartilaginous fardness, whilst in some there were calcaroous particles.

There is little to be hoped from treatment beyond attention to the general health, warm coething, nonrishing diet, chloride of amnonium, preparations of iron, cod-liver oil, and pure air. When there is discusse of the joints the surgeon's aid may be required, and if the complaint has a syphilitic origin, it will demand special remedies. Dr. Budd gives as his experience that he has more with more than one instance where recovery took place, the possible morted matter passing off with the bile, or becoming absorbed.

Fully Lines. This form of enlarged liver arises from the accumulation of oil within its selectance. The organ increases uniformly

^{*} Bodd on the Liver, 1882, p. 201.

in size in every direction; it is smooth on its surface, of dengly consistence, and on examination, after death, it is found to be pale in color. No matter how severe the discuss may be, the secretion of bile is not interfered with, therefore jamilies in uncomplicated cases, does not occur; the superficial veloc of the abdomen are not enlarged, and there is no assistes.

Symplems.—These are amenda and debility, languor, insitude, flatulence, irregular bowels, and depression of spirits. The skin is bleodless, and has a sallow or waxy appearance, resembling fine polished ivory, or a common wax model. Most of the constitutional symptoms are "eften due for the next part to fatty degeneration of other organs, and more especially of the heart."

The speece is rarely enlarged, and the complaint appears to arise chiefly in connection with phthisis, or some other wasting distorder.

Thus/asset.—This consists in attention to the digestive organs by alkalies, regetable bitters, and aperients. The waters of Ena, Vichy, and Schwalbach are to be recommended. When assenia is the leading feature, the preparations of iron, especially the ferrior ammonia citrus will be found serviceable. The treatment, herever, resolves itself into that which the primary affection requires

A simple hypertrophy of the liner has occasionally been met with in diabetes.

Assumes of the spleen in children have been in my own personal experience almost exclusively confined to the lower classes, and even among them they are not of frequent occurrence.

^{*} Discouse of the Liver, by C. Mandisco, M.D., 1977, p. 49.

^{† * 6)} cases of death returned as the to spices diseases in England, among sale subjets, which occurred in 1877, only 5 were under the years of age; and of 61 femile.

sometimes meet with splenic disease in children in this country, and more especially in dispensary and hospital practice, where poor and insufficient food, bad ventilation, and burned houses have exceted a predisposing effect." They may be described as those of enlargement and hypertrophy, arising chiefly from congestion and inflammation.

The elastic structure of the spleen renders it susceptible of distension from slight causes, and hence any affection of the liver or arrested skin action may increase its bulk. If these disorders contiane, the speen fails after a time to propel the blood coward, and, from such arrest, permanent congestion and enlargement follow; and sometimes inflammation and abscess.

There is no organ so variable in size and consistence as the spleen. "It is much smaller in elderly than in young people—indeed, it may waste away in old age to a pale relie of not more than two or three drackma in weight."

In amyleid or lardaceous degeneration, the Malpighian corpostes may alone be affected. The spleen is enlarged, and its density is increased. On section, clear waxlike little bodies, of variable size, having the appearance of boiled sage, are to be seen in these corpuscles, hence the disease is known as the "sage speen," which is frequently seen in those children who die of pathisis. There is another variety of the amyloid spleen in which the pulp is chiefly involved. It appears to be an advanced condition of the former affection, the disease extending from the corpuscles to the pulpy parenchyma.

The general symptoms are not well marked, but if the spices has attained any considerable size, there is usually some amount of pain or tenderness, or distension in the left hypochondriac region, or over the epigastrium, extending through to the back; and there may be cough or dyspaces on lying down; but these are only occasional symptoms. The child is sallow and pale; the tongue is bloodless and clean; the pulse is weak and frequent, and

telly 12 were under five years of upc. Under lifteen years of age it is extremely move. In London, in the year 1877, of 8 cases of death in union, 1 were under five years of age,"—Factist Amount Report of the Registrate General, pp. 152-118.

there is loss of flesh and strength. The urine often contains neutes. and the motions are offensive, deficient in lols, or they are loss and contain manus. Sometimes they are constiguted. In some enses there is scarcely any inconvenience beyond that caused by the increased size of the abdonus from the spenic tumor, the appetits and digration being excellent. In two cases that came under my notice, although the tumor reached below the umbiliem in one case, and nearly filled the abdomen in the other, there were so noticeable symptoms beyond the inconvenience of a bulky mass in the abdomen. The complexion was sallow in both cases, but these was no headache, no fever, no prin in the side, or shoulder, which is often mentioned by writers." In other instances rein is complained of on pressure over the spienic region, the child have the left side with its knees drawn up, and is restless and deeplox at night. An oplemic disease progresses, and the blood become more impoverished, an anomic brait may be heard over the law of the heart. There may be swelling of the abdresses terminating in necites; but this is very rare, owing to the thick capsule of the spicen not admitting of the explation of any fluid, as happens in some affections of the liver and intestines. The spleon, being out of the way of the portal circulation, has no direct tendency to come melter; but when there is cirrhosis, or any mechanical ism pediment to the venous rireulation in the liver, the spleen may become enlarged. When the spless has attained a very large size, the superficial veins become distended, in consequence of an interference with the circulation through the desperableminal research In very long-standing cases of splenic disease, the parient become ancemic, from a deficiency of red coppusates in the blood, and an excess of the white. In one disease of the spleen there is an excest of white orposeles in the blood (leukermin) over the red, just as there is in disease of the lymphatic glands, and there is assembly with it at the same time a new growth of lymphatic tisms in the sphoen. Hence the tendency to pallor, to usdema of the finds, to

[&]quot;The shoulder-top pain and the move tendermos in those discuss on online I better they are in liver discout, to an expension of initiation or influenced from the discisor legger, along its process; arterings to the mark of the per capes. Radderson, M.D., Brit, Med. Joseph, etc., it, 1874, p. 371.

has northing from the gums or rusal passages, as the consequence of these changes in the circulating blood. Under a continuous of these symptoms the child sinks from exhaustion, or death is often due to diarrhous.

Pollobyy.—As we are unacquainted with the functions of the splean, we are in doubt concerning the thorry of the mortial changes to which it is liable. Its targislity, probably, depends upon some relaxation of the vessels and tissues of which it is composed, as well as to a sorre parisis. The fact of the splean laying been removed from the body without impairing the rost of the functions would go far to substantiate the view that it has no influence upon the secretions of the stemach or panersus. Still, Michael Foster writer as follows: "After a meal the splean instrume in size, reaching its maximum about two hours after the taking of food; it remains swellen for some time, and then returns to its normal bulk."

"It is a point of considerable interest that the spleen, the lymphatic glasses, and Peyer's patches all suffer involution at the same period of life—about fifty. At that time the spleen grows smaller, the lymphatic glands waste, and Peyer's patches smooth down and less their pseuliar structure; and that is about the period of life at which the diseases, and especially typhood fever, in which these thrus parts are involved, cease to be common."

Some interesting observations are mentioned by Swedenborg.;

Comes.—Enlargement of the spires is frequently due to ague, and honce mostly prevails in murshy districts along with intermittent fever. Louis, Murchison, Warburton Begbie, and many other observers have noticed it discused in typhoid fever. Discuss of the liver, as circlesis, or whatever obstructs the circulation of the spices, may increase its bulk. "It is often greatly enlarged in European children who are resident in the tropics." This is most likely a state of more hypersemia, but long-continued congestion ultimately leads to enlargement and induration. Obstructive discuss of the heart, emphysema of the lungs, by exasing dilatation of the right excities of the heart, and cente tubercolosis may in-

duce congestion of the spleen. In the latter affection I have seen a few caseous deposits of considerable size both in this organ and the liver, when the lungs have been studied with similar intercles and the diaphragm honeycombed.* An enlarged spleen, associated with rickets, came under my care in April, 1880, in the case of a child a year old, the spleen reaching to the llima below, and on its inner border to the umbilious. Although mechanical concestion may be one cause of the hypertrophy, it more frequencle arises from some morbid condition of the blood, from endocarditis, giving rise to infarctions, from syphilis, from feveral from amenda, but in many instances it undergoes enlargement without assignable cause. On section it is soft, vascular, and of a dark-ost color. A bealthy woman and her husband had six children, these of whom had disease of the spleen. One shild, a hoy, was notical to have a large spleen when fifteen months old, and he lived to be nine years and a half old. Epistaxis began at the age of five years, and continued to recur periodically about once a month. A second child (whom I saw in August, 1880), ten yours of age, bed from the nose in the same way, and quite as profusely. A third child, a girl one year old, had an enlarged spleen, extending to the ilium. and untillions. It had only been detected five weeks. All these children were ravenous for food. The spless has also been found hypertrophical in some cases of leacocythomia (splowie bucoytheand, and in this affection it uttains a great size. Dr. Taylor has recorded the case of a boy, twelve years of age, who died from this disease, and whose spices was found to weigh 51 omces. **

Diognosis.—As the abdominal wall in children is not covered with much fat, and the muscles are thin, the diagnosis of enlarged apleen is far easier in them than in adults. Some care, however,

[&]quot;Theorete cours, for the most part, in the splices only in some universal referentorie; it occurs town frequently in children than in solute, in the proportion of 40 to 13. 7. "In nearly all affections of the opten small horseerings is a common sympose, and among ancient physicians, and to this day among the popple, repeated blooms of the nose, especially if from the left manual, is taken for an above purious symposus of each disease." — Nicosyn's Tection of Prenticed Medican, 1813, vol. 1, p.783.
19 Path. Terms., vol. 229, p. 253.

is necessary not to mistake for an enlarged splann an abdominal tumor caused by enlargement of the kidney or liver, or by discove of the mesenteric glands. In forming an opinion of tumors in this situation, it is well to glance at the anatomical position of the splan. It lies hidden in the left bypochondrium under corer of the ribs, between them and the stomach. When healthy it cannot be felt through the abdominal parieties; if it can it is discussed. Moreover, it is influenced by the respiratory movements.

An enlarged spleen may extend inwards to the epigastrium and umbilious. In some children it reaches down to the spine of the ilium. The tumor is smooth, elastic, and firm, and, being situated just beneath the integrament, its shape and firmness can generally be well ascertained. In cases of difficult diagnosis the history of agus would be of much assistance. Sir W. Jenner has seen a tumor, supposed to be feeal, which turned out to be "a big spleen, and the child was purged for it till it had bloody stools." Tumors which are due to enlargement of the kidney do not cause any projection posteriorly; the expansion takes place in the direction in which they meet with the least resistance, and that is always in front.

Transacat.-The general health will require careful attention to maintain it at the best possible standard. In this we must be guided according to the circumstances and surroundings of each individual case, the strength of the child, the stage at which the disease has arrived, and the complications it may have produced, If inflammatory symptoms are present, and there is any degree of arnte pain, thirst, dyspoon, etc., poultices and fomentations, and even two or three backes, applied over the affected part, may be necessary to reduce congestion of the gland. If the skin is hot and dry, and there is any degree of fever, saline apprients (Form, 5-41) to unload the bowels and drain the portal system will be seeded. When all acute symptoms have departed, the use of seline externally, in the shape of contment (Ung. Iodi.), and the lodide of petassium internally may be demanded. Very frequently a eachectic state of the system exists, arising from ague, syphills, or rickets, and these conditions must be met by suitable remadies, such as arsenic, mild mercurials, uninine, etc., continued for a long

Clinical Lemmas on the Diagnosis of Extra-policic Tomas; of the Abdones, Brit. Hed. Journ., 1969, vol. ii. p. 40.

² See Chap. XXIV, Hydronephronic.

time. Mr. Tyson, of Folkestone, has recorded a "Case of Syphilitic Enlarged Sphen in a Child." At two years of age, the sphen reached to the crest of the illum, and marrly to the mulcileas. A grain of gray powder was given night and morning, and one grain of indide of potassium with ten minimum of the sympol indide of iron, three times a day. In three mouths the sphen was smaller, and two mouths later it only extended an inch below the margin of the riles. The remedies were given for about a year, when the sphen was imporceptible, and the child's hadde excellent."

In a large number of cases, assemia is so marked, and the constitution so reduced, that the patients lose fieth, and gradually sink away exhausted. Chalpheutes are of course indicated.

The renal affections of children are less frequent than many of the allocents to which early life is liable, but there imags about them an obscurity which, in a physiological point of view, is perplexing, and in a clinical one, difficult to reconcile with our knowledge of disease, and of the active functions which the kidneys passess when health is continuously maintained.

In order to understand the disorders to which the kidney is liable, it is well to giance at the renal apparatus in health, and to see how the different structures are concerned in the climination of morbid elements from the blood.

Beale and Johnson say the water is first eliminated from the blood, and the urine salts are gradually added as the water posses

[&]quot; The Linear, 1880, vol. 10, p. 653.

down the tubules. Ludwig, Bruston, and others, entertain the view that the water of the blood, holding the different salts in solution, is first squeezed out in a very diduted form, and that the absorption of water goes on through the spithelial lining of the tubules, the urine thus becoming more concentrated as it passes down the tubules. The former assert that the function of the spithelial cells of the tubules is so exercte urine salts, while the latter assert that their true function is to absorb water.

There are two facts which stand in a very significant relation to these views: one, that after equious draughts of water the epithelial cells do not exert themselves in absorbing water freely, and so the crites is copious and of low specific gravity, while during thirst the spithelial cells absorb water mose actively, and the urine is seanty and contains excess of salts. The other fact is that in circlesis of the kidney, where the tubules are denuded of epithelium, the urine is copious and of low specific gravity.

The importance of this subject practically, is the question as to whether the urine, when first squeezed into the glomerall, is albuminous or not. According to the view of Ladwig and others, it is primarily albuminous in a faint degree, and the albumon is real-subside along with much of the water by the epithelial cells of the tubules. According to the other view, albumon is thrown out along with the urine salts in disease of the urinary tubules. The question has not yet been settled, but the view of Ludwig seems more feasible, and consistent with the known fact, that albumen appears in the urine when the tubules are discared.

On the assumption that the spithelial cells normally realsorb albumen as well as water, we can readily understand how, in certain conditions, albumen is present in the urine. When the telesias are the subject of inflammation, they lose their power to reabsorb albumen, consequently albuminaria is constantly found in tubular nephritis, as we see commonly after scarlet fover. We can therefore understand how temperary durangement of the spithelial lining of the tubules any be followed by the appearance of albumen in the water. Such a condition may exist without the kidneys being unressarily organically diseased. In cases of albuminaria, then, the question arises, whether the passage of albumen in the water is due to conditions of temporary derangement, or to structural disease of the kidneys.

In the treatment of sick children, a constant observation of the

urine is as important as in the management of discuss in adult life. At all ages morbid conditions affect the secretion of the kidneys, and childhood is no exception to this rule. Even when not on the sick-bed, the insidious effects of errors of dist, and other had habits, are first shown in alterations of the amount of daily exception of urine, and in changes in its constituents. Intemperance, the chief vice of man, directly affects the kidneys, so that the reveiler longs to make water after a banquet. Gluttony, and the preference for rich, rather than wholesome food, are the commonest failings in childhood. Hence the turbid urine passed by children subject to gastric and intestinal irritation through overlandingness in sweets and pastry. Ignorance of the evil effects of draughts of cold air, and wet first, renders children liable to catarrichal affections, which produce changes in the urine.

For some obscure reason, calculus is not rare among bors in the humbler ranks of society, possibly because their skin and lungs are hardened against chill, whilst during enstumary exposure to cold their kidneys become congested; on the other hand, children of gentle brooding, have often weaker lungs, but through afficient elothing they are less liable to contraction of the bloodyessels of the skin, and to consequent increased pressure on the kidners. Lastly, it is in childhood that reflex and emotional influences act so strongly on the renal secretion. The phenomena of enursis, and of loss of control over the bladder, from the very fear of that accident, are almost possible to childhood in civilized lands, where the adult, even among the lowliest, learns self-control, or through experience, adopts precautions. An antiquated, coarse expressice, common to most countries, shows that in former less refined states of society the involuntary escape of urine, as the result of fear, was not rare in adults. It is physiologically most interesting to observe, on the other hand, the great delicacy of even very young well-bred children in this country with regard to micturition. A gentleman taking his little girl out for a walk, is often astonished to find that when the child shows symptoms of duite to pass water she cannot be personaled to do so in the open sir, and indeed feels much burt at any attempt at personsion of a kind which previously she has only heard from her nume or mother. An infant is often assisted in micturition by being hummed to, or coaxed, a practice very similar to the method exployed by a rider when he desires his horse to stale at a moment convenient to himself.

Since very slight disturbances produce feverishness in childhood, and since high temperature involves the excretion of concentrated urine, that fluid will almost always be found to be above the normal specific gravity in a children's ward, its acid reaction is likewise well marked under these circumstances. In fever among children, the thick and almost milky urine, turbid when passed, not not rely turbid when cool, is highly characteristic. The turbidity is dissolved but slowly on boiling in a test-tube, for it is due to the trate of soda, insoluble in cold, and only aparingly soluble in hot water. In many febrile diseases, however, children pass clear urine, which on cooling throws down the well-known deposit to readily redissolved on hoiling in a test-tube. In this deposit the more soluble urate of ammonia predominates.

The urine of a child suffering from acute scarlatinal pophritis is very rich in morlod products. It is smoky, or almost brothlike, from the presence of altered blood, and throws down a deposit rich in spithelial casts, and in the beautiful light-yellow rhombodal errstals of uric acid. Such urine must be carefully examined day after day, and its gradual return to a normal condition will be a valuable guide to the treatment of the case. Phosphates are often found in the arine of neevons and sick children, and in such cases the fluid may be copious and below the normal specific gravity; exalutes may also be found in pale abundantly excreted urine. Mucus is frequently deposited in the urine of children suffering from puraplegia, from spina-hifida, or from local causes, such as calculus, and is an unfavorable symptom, since it may denote serious changes in the genito-arinary tract; the presence of pus is due to the same causes as in adults. In mass of enursis the condition of the arise must be carefully examined; when a morbid sait is discovered the administration of a drug which counterarts its forwation often cares the patient, as the presence of such a salt in the bladder may alone cause the complaint.

That attention which is now paid to the wine in adults when ill has not extended as far as it should do to the examination of urine in children. With the exception of the albuminum of scarlet fever the profession as a body knows little of these modifications of the urine produced by disease in children. There seems to exlat a widespread impression that changes in this secretion are only important in adult and advanced life, an impression which, to my mind, is erroneous and ill-founded.

In the present state of our knowledge we are not able to draw any satisfactory inferences from the specific gravity of the urine in children. I found that in 242 cases admitted into the Sunaritan Hospital under my care, the highest specific gravity reached, was 1014, in four cases. I. Epilophiad senoures; 2. Congretive broduche; 3. Taberculosis; 4. Cutarrh. In all these four cases the urine was pule, scanty, and very acid. The lowest specific gravity was 1000, in a boy six years of age, on the fifth day of typhold fever, when it became pule, clear, and alkaline. After taking small doses of hedrochloric acid for five days, the reaction became acid, and the specific gravity reached 1018. The urine was never turbid, nor threw down a deposit, notwithstanding that the temperature reached 193.6°. In states of defaility, and in some cases of mitral disease, the specific gravity fell to 1010. The average specific gravity of the whole 242 cases was 1923, and instances of this were furnished in anomia, debility, pleurodynia, rickets, phthicis and headache. In only 32 was the specific gravity under 1020; 57 had a specific gravity of 1020, or over. In 34 there were phosphates. In none was sugar found. In three cases only were there large "carcane pepper crystals," and these were in: 1, A case of tuberenlosis, where the urine was highly seid, pale, and scanty. 2. Lebular pressuonia. 3. Chronic alleminaria. A girl suffering from chronic mitral disease became very nervous, and afterwards her urine threw down a great deal of uric acid.

There was only one case of chronic albaminaria in the whole 242 mass, and this occurred in a strumous girl, nine years of ago. The specific gravity varied from 1016 to 1020, and the microscope showed irregular-sided granular easts, some urle seed, epithelial cells, and broken-down blood-corpusoles.

Conjection of the kidneys is one of the most important disorders to which these organs are liable. It is a common attendant on many allowants of children, passing away with the recovery of the patient, and leaving neither inconvenience nor structural change helped it.

In measter and scarlatina, as well as in many inflammatory disenses, there is a determination of blood to the internal organs, and active congestion of the kidneys is of frequent occurrence. In measter it is often slight; it is notably more marked in some cases of searlet fever, and there is a considerable amount of blood with casts of the uriniferous tubes and spirhelial collage that the urine is albuminous. This is a point I shall more particularly consider when I come to speak of a state of congestion of the kidney, brought on, not by the scarlatinal poison, but by exposure, had living, impure air, and the strumous helds.

The precise form of congestion, as in adults, is most common in miral regargitation, and other valvular diseases of the heart; in employeens, pseumonic conditions, pleuritic effusion, or disease of the liver, pressing on the room cava. This form of venous congestion is owing to an impeliment through the systemic veins. The passage of blood through the kidney is slow, and congestion takes place, the urine is stanty and high-colored or turbid, and more or less impregnated with allounce. In obstructive disease of the boart, the fulness of the venous system distances the renal wrins, and the Malpighian capillaries becoming engarged, a transmidation of serum takes place through their walls, readering the urine alluminous. Whose the walls of the capillaries are ruptured from this coverdistancies, blood is mixed with the urine, and blood casts are visible.

The first effect of passive congestion is to cause enlargement of the gened, and ultimately contraction and atrophy, the surface of the kidney becoming uneven, and finely granular as the westing process goes on. (Johnson.)

The transcent consists in relieving the circulation by hydragogue catherries, absolute rest, and tapping of the chest or alalomen, if there is a large accumulation of fluid, and it cannot be got rid of

in any other way.

Experimental research has long demonstrated the fart, that a ligature placed round the renal vein, obstructing the return of blood, cames the kidney to increase in volume, and the urins to contain albumen, casts of the uriniferens tubes, and renal epithelium. Hence the liability, in inflammatory disorders, and checked cutaneous action, for the kidneys to become rougested, like other organs, and so to create a disturbance in the intricate and along adapted circulation through the Malpighian tufts, and plexus of capillaries, which surmand the uriniferous tubes.

Some cases of intermittent off-measurers are due to congestion of the renal vessels, or to loss of tone in them. An interesting case of this kind is alluded to by Dr. Moriey Rooke, of Cheltenham. There were no renal products under the microscope, the albumen disappearing with rest, but returning when the patient assumed a vertical position."

In children, as in adults, the injudicious use of mercury may produce temporary albuminuria, either by setting up some blood change, or inflammatory condition of the renal atractures. It passes away when the remedy is discontinued. Other irritants or substances, which find their way out of the system by the kidneys chiefly, as lead and alcohol, have the same effect.

Acute Desgramming Nephritis,-The disease follows the same course and presents similar symptoms in children to adults. The symptoms are those of general febrile action with a temperature which may reach 104,7 with quick throbbing palse, thirst, headache, and loss of appetite. There is pain in the loins and legs, and in a few days the face is pale and shrunken, the cyclids are puffy, so that the eyes cannot be seen, general anasarva or dropey sets in early, and the hands and lower limbs are ordenatous; efficient into the pienral ears, pericardium, or abdomen, are common, and pregnamia is operationally present. At first the urine is scante or almost entirely suppressed; it is dark from the presence of blood, and contains a thick selliment. If there is pain across the form, or deoperated tenderness on pressure, more or less blood will often he seen, or detected under the microscope, with tube-casts, and regal epithelium. The patient is restless and talkative in sleep. and if the urine does not increase in quantity, the poisoned elements in the blood will sometimes lead to convulsions, delirium, or coma. Convulsions are, however, infrequent in the allumintrin of children. As the disease progresses, and congestion of the kidneys diminishes, the prine becomes pale and increased in quantity, and the answerea gradually disappears. Notwithstand-

Ivit. Med. Journ., Manchester Meeting, Aug., 1877.

See Chronic Dospunantes Nephritis, p. 264.

[&]quot;Under ordinary circumstances allowiness holies do not diffuse through summer than the list in hos been shown by Hernard, Parry, Stockels, and others, the aforment of ages will gave out through the kidneys, while the aforment of blood down not do needed similar conditions." (Dr. Lander Brancon).—Proschioer, June, 1871, p. 427.

[†] This high temperature appears to be unusual. Dr. Dicklasson mentions that he has no thermomenic spoord, at the cunset of this disease, of more than a few points above 100°. When encomplicated, he has known the temperature to range for many works between 17.5° and 1955°.—Diseases of the Kidney, part 2, Albumium's, 100°, p. 228.

ing this, the albumen may be equally great in amount, and any error in diet, or cold, will renew the renal congestion and humaturis.

The microscopical appearances of the urine show epithelial casts of the uriniferous tubes. In these casts are to be seen blood-corpuscles and renal gland cells, hesides small and large hyaline casts, but these are often insistinct, and cannot be seen for weeks together, even when there is a large amount of albumen. The large hyaline casts may be absent altogether (Johnson). As the disease goes on, oily casts and cells are detected in the tube-casts, indicating that the secreting cells of the kidney are undergoing fatty change."

The ones of this affection in childhood, are most frequently due to scarlating and to suppressed action of the skin following exposure to wet and cold. When the rash of scarlet fever is out, or the skin is desquamating, cutaneous action is checked by cold, and a merbid process is set up in the kidney. The circulation being impeded, the urlnary constituents accumulate in the blood and lead to dropsical effusions. It is generally admitted that the more severe the threat affection the less likely are the kidneys to become affected; but it must be borne in mind that when the throat is very sore the patient is treated with more care, and is not so likely to be exposed to cold, which would cause or aggravate kidney disease. Scarlatinal dropsy is most frequent from the tenth to the fourteenth day, but it may be delayed much later. In two cases under my care, about the same time, the symptoms came on in one case at the end of the fifth week, and in the other case at the seventh week.

Nephritis in children has also been observed in connection with pacumonia, rheumatic fever, small-pox, typhoid fever, chronic dyspepsia, and the consumption of indigestible food. Next to scarintina, diphtheria and measles are the most common causes.

Scarlating then is the most frequent cause of acute rephritis, the kidneys being irritated as they assist in the renewal of morbid products from the blood. This unboulthy stimulation throws upon these organs work to which they are unaccustomed, and as a consequence they become congested, and the tubes choked up with

^{*} For further information on this unifort the reader is referred to De. George Juley, sur's Lectures on Bright's Discour, 1873; Dr. Boberts on Unitary and Reput Discour, 1877; and Dr. Dickiesen on Discours of the Kidney, part 2, Albaminaria, 1877.

explation. If, at the same time, the patient is exposed to wat and cold during the shedding of the saticle, symptoms of arms recall disturbance are set up and deepsy follows. Dr. Dickinson writes: "That at the Children's Hospital where children are treated up to twelve, a series of 105 cases of albuminum commeted apparently with recal inflammation, gave 75 where the distrike was traced to scariation, 3 to measles, I to crysipeles, I to cente rhomatism, and I in which it came on in the course of crysma; 5 from cold, and 17 from uncertain causes made up the tale."

Boys are more liable to searchtinal dropsy than girls, just as adult under are more prone to kidney disease than female. The greatest frequency in children is between the ages of five and fifteen. "There are two periods which are especially assemble to the disease. The scarlatinal form is most common under ten years of age; the form which results from cold is especially upt to occur between twenty and thirty."† The association of tuberculosis with this disease is extremely uncommon.

Philology.—In consequence of suppressed skin action the kidners become congested through having to take on increased finetional activity, whereby the organs become congested and avolen-

Hyperplasia of the spithelial cells in the tubules then takes place, and these cells are iscapable of separating the solid uniance constituents, which, remaining in the blood, give rise to the wellknown symptoms already described. Hence effusion takes place in the various thoses and scroom sacs of the body. The blood undergoes changes, in becoming poor and thin, falling in specific gravity, whilst alleamen and blood appear in the urine from dilatation and rupture of the renal capillaries. For some time area is eliminated by the confiring and discribes that cases; but when these functions fail, the gradual arcumulation of excrementators urinary compounds in the blood occasions convulsions or com-

Model Anatony.—If death takes place during the some stage the kidneys are found composted and enlarged; they are of a darkred or chocolate color, the correx is mottled with spots of samula and is evolutioned, and the modulary cones are dark and congested. The orioifdrons takes are crowded with epithelial cells and blood, the walls of the capillaries are thickened, and coupstion of the privis of the kidneys, orsters, and bladder is found in

Discuss of the Kidney, by Dr. Dickinson, part 2, Albandauria, p. 52b.

[†] B., puri E. Alberateura, p. 264.

addition to effection into the scrous sacs. After a variable period the kidners in some cases undergo degeneration (chronic diogeneration applicate).

Proposois.—When the secretion of urine is free and there is not much blood or albumen mixed with it, the prognosis is favorable, and many cases due to scarlatina or massles completely recover; but if the albumen is in excess and the urine is deficient in quantity, or the child is of a strumous constitution, the prognosis is bad. The subjoined case is a good example of neutral desquarantive nephritis, terminating in permanent albuminaria and chronic charge of structure.

E.S.—, set. 9], a fast-growing, strances looking girl, was admitted into the Samaritan Hospital noder my care on June 15th, 1875, suffering from acute desquamative nephritis and asserted. The parents stated she had never had scarled fever, nor had the means prevalled in the house or neighborhood. The case seemed due to cold and exposure. On admission, the eyes were almost elseured from adema of the lids; the arms, legs, and thighs were tense from subcataneous infiltration, and there was free finid in the peritoneum. There was slight effusion into the left pleural as labout a quarter of a pint); the first sound of the heart was a little prolonged, and looker than usual, but the valves were healthy. Temperature 100 1%, pulse 120, respiration 32. The mother said that she noticed her daughter's face swollen in December, 1874, but she had attended school regularly till a mouth before admission.

The urine was high-colored and turbid; reaction, said; sp. gr. 1010; it was thick and clotty on boiling, and the addition of mitric acid rendered the whole an albuminous curollike mass, affected to the test-tube.

June 16th.—There was much more ordents of the feet and legs, and the temperature was 102.2°. The urine was thick, scanty, and dark-colored; only twelve conces were passed in twenty-four hours (although she drank freely of cold water), sp. gr. 1080; on the application of heat, the urine congulated in large and divided clots. The addition of nitric acid converted it into a thick, somy mass, which admitted of the tube being inverted, while only a little fluid escaped. Under the microscope, there was not a trace of blood-corposcle, urinary cast, or epithelial cell, which is musual with this albuminous condition of the urine.

She was ordered a mixture of fincture of digitalis with nestate of potach, and compound julap powder occasionally.

19th.—The temperature had rison to 194°, and the pulse to 140; the auscarea had much increased, and there was great stuper and drowsiness. A third of the urine was albumineus, and on standing all night looked like lurm. The microscope new showed large spithelial cells, probably from the straight portion of the tubes, and numerous blood-corpuscies, some of them altered and shrunken; a few spithelial cells from the convoluted perties of the kidneys, and two short and small granular casts. These was now acute nephritis, with a limited degree of desquamation.

Three days later, forty-four ounces of pale urine were passed in twenty-four hours. A few hyaline-looking casts, large and small, with here and there a renal gland cell, were seen under the microscope. Bark and hydrochloric acid were now substituted for the previous mixture. At the end of another week, seventy-free ounces of similar urine, with a low specific gravity, were passed in twenty-four hours. The timeture of the perchloride of iron was given in ten-minim doses three times a day.

During the remainder of her stay in the hospital she passed above the average amount of urine, as the healthy functions of the kidneys were in slow process of restoration.

On the 24th of July she left the hospital feeling quite well, and presenting no trace of dropsy. The presence of allemen was doubtful.

On October 9th of the same year, the patient was readmitted with symptoms of acute desquamative nephritis. There was much amsarca of the face and limbs, which increased for a few days after admission into the hospital. The urine was highly albuminous, and elected like cream on the sides of the test-tale. The deposit contained granular casts, indicating the desquamation of cells already morbid; moreover, numerous cayenne paper grystals of urio acid were found, proving imperfect elaboration of the nitrogenous principles in the blood, from reduced functional activity of other organs.

In November she cought cold, and had an attack of neute retal congestion, followed by a large quantity of bloody urins, of a bright claret-color. At the close of the month, the urine was still dark, containing blood-corpuscles, broken irregular grantlar casts, and some fresh renal cells. For the first time I detected ircrewed impulse of heart, and intensification of nortic second sound. The 24 of a grain of perchloride of mercury was added to each dose of the mixture. There was a slight reduplication of the first sound over the interventricular septum, and the spex beat was lower by half an inch.

January 11th, 1876.—A careful examination of the heart revealed the following condition. The second sound was intensified to a certain extent over the aorta, and to a greater extent over the pulmonary artery in the second left intercostal space. There was occasional doubling of the second sound over the come arterious; there was no doubling of the first sound anywhere; evoluginspiration was audible over the upper lobes in front, but not behind. Apex beat in fourth interspace, and impulse extended to outer side of nipple. The pulse did not present the feeling of tension, and when the finger was lightly applied to the radial artery it felt the streke and collapse. Sphygmagraphic tracings showed moderate tension; greatest sweep at about 150° to 200°; systolic rise was not anywhere greatly prolonged.

27th.—At her mother's request, the patient left the hospital, her general health was good, and all dropey had disappeared. The urine was clear and acid, sp. gr. 1020; it contained only a trace of albumen. This favorable change was attributable to the perchleride of mercury, which she had continued regularly up to this

time.

June 11th, 1877.—She was perfectly well in health, and had remained so ever since January, 1876. She had never any headache, sickness, or diarrhous, and her mother considered her as well as at any time of her life. She was fed on eatmeal porridge and milk every morning, and had ment three times a week.

Analysis of Urine.—Clear bright yellow, with mucous cloud; sp. gr. 1024; faintly acid reaction. Became very milky with heat, and the cloud was partially cleared with affervescence by the addition of a few drops of nitric acid (phosphates). Albumen a

sixth part.

The sucroscope showed ordinary squamous spithelium, and a quantity of hyaline tube-casts, but they were very indistinct. The high specific gravity is unusual with such albundaous urine."

^{*}There are several points in which this case is both suggestive and instructive, thereing as it does, in a very striking manual, that the presence of a large transmit albumou in the uring is not incompatible with active growth of the body, and a good

As a sule, shildren recover more frequently from the dropsy of scarlatina and other febrile diseases, than from that which is due to cold and constitutional causes. Usually the disease terminates in six months, but it may assume a chronic form, and he indefinitely protracted; the interstitial tissue of the kidneys increases, and contraction causes. Of 50 fatal cases under the age of exteen, 28 died from diseases of the respiratory organs, including prenmonia, piourisy, brenchitis, and empyense. Of the remaining 22 cases, death was caused by arrende convulsions in 8, by plentile effusion in 8, by conditing in 3, by peritonitis in 4, by pericarditis in 1, and by sloughing of the scrotum in 1. (Dickinson.)

Now as to the general management of these cases. When the primary cause of the disease can be ascertained, we may do much in mitigation, or core of the symptoms, by directing careful attention to all those points which bear upon the original makely. It the alloanen be due to presoure from morbid growths, or so an enlarged liver, we know the best plan to adopt in mitigation of the crid; and if the thoracio organs are unhealthy, they may induse renal changes through obstruction to the circulation. We may excite the action of the skin by the warm bath, and by displaced is; we may relieve the portal circulation by officient pargation, and thus we can indefinitely prolong life if there is no hope of saving it. But all drugs and therapeutic agents are secondary to

main of health. When such cases as these exeminately evide under close overrains and appartunities are affected of studying their matter and progress, we may reconcide evident energies to the american, that whenever a large community alternate is delly asparated, from the blood for many security, it meet indicate path/logical changes in the recoil organs of a chronic and increately matter.

In is remarkable, and very exceptional, that the spanised unitary exceen should case to give rise to any constitutional symptoms when there was no element discharge from the strength or bounds going on, or such our the impurities from the system. There was no flatalized, dropopout, or any complaint whatever, and the identicable, builtly fratery, well the low of the compounts indicated a return to health, though the patient was living in a poor home, without much care or attention in the

In this case we may explain the mentistener of allocations with good general leadsh on the hypothesis, that a mild arbecture inflammation of one, or even both hidrays we at one time going on. Such a condition is not incompatible with an absort particl functional activity of the hidrays in other cospects, and may be compared with channel extents of the amount normalization of the same and broach, where inflammatory products are discharged for pasts. But the fact must not be reophyshed, in this and similar raises, that continued congression, whether it he inflammatory or otherwise, alternate tends to anothly the matrices of the hidray, and to alter the glouddat structure, we that in time it leads to attempty and contraction of the organ.

diet, for the closest relation exists betwirt the solids and fluids taken in as feed, and the condition of the urinary secretion.

Treeland of Acute Desparameter Nephritis.—The patient should be kept in had, and the temperature of the spartment maintained between 65° and 70°, but well contilated, and free from currents of cold sir. In all cases, and particularly where the secretion of urine is sensity, diluent drinks should be taken freely, and the dist be very scarety. For children, milk is the only nourishment necessary, as it does not irritate the kidney. If the milk dangrees, or the patient tires of it after a time, or if it deranges digostion, or causes constipation, a little weal broth or mutton broth must be substituted, and barley water, sugo, or arrowrood are useful, but in every case the patient must soon return to a mik diet. Absolute stimulants should be prohibited.

To reduce the inflammation, cupping, or leaches to the loins may be necessary, if the shild is strong and full of blood; but if there is much homorrhage from the kidney the patient may be too weakened, and operious and disphoretics will be safer. A disphoretic mixture containing antimony, or a solution of acetate of ammosin, will determine action in the skin, and relieve any dropoleal offssion that may be present. It is important to unload the lowels well, and for this purpose, a purge occasionally of compound jalap powder, will relieve arterial tension if present, and rouse the kidneys to freer action. A fair allowance of fluid should be taken to wash out the tubes, and to prevent their obstruction. In this way the compostion of the gland is relieved, and there is a better chance for all the constituents of the urine to escape. "Of all diureties water is the best" (Dickinson), and it may be taken to the extent of two or three pints daily. The bitartrate of potash drink. flavored with lemon and sweetened with sugar, is very agreeable; whilst it helps to clear the renal channels of morbid secretions, it keeps the bowels free, and also assists in relieving the contamination of the blood.

A mixture of citrate of potash and tincture of digitalis increases the quantity of urine, and, so far as my experience goes, has no tendency to aggravate renal congestion. It is a favorite remedy with me when the accretion is scanty and high-colored, or contains blood, although Dr. Dickinson is of opinion that digitalis, by adding to the force of the heart, may increase the discharge of blood. In the form of infusion, digitalis is a good discretic, and our or two drachus may be taken three times a day.

In the early stage of the scute affection, warm boths, or the hot vapor-both, may be used with great advantage, and they are purtionlarly suitable for children, if the action of the skin is defective, and there are any signs of cerebral oppression. The streating that eneues brings immense relief to the system, unloading the capillary circulation, and lessening the distension of the resal voses. The laths may be employed every night on going to bed, for the first few nights, and then less frequently. The temperature may vary from 98" to 100", and the child may be immersed from 10 to 15 minutes. Dr. George Johnson speaks highly of a wet sheet and blanket bath. "A short is urung out of warm water, and the patient, either naked or covered only by a shirt, is enveloped in the wet sheet up to the neck. Then there or four dry blankets are closely foliod over the wet sheet. He may remain thus packed from two to four or six hours, or even longer. Recently, a loy in the hospital with acute renal discuse and almost complete suppression of urine, consequent on searlet fever, was kept parked incessantly for four days without sorious discomfort, and with great relief from very discressing and alarming symptoms. When he left the bregital all traces of his malady had disappeared."s

If head symptoms in the character of convulsions or come supervene, we may generally attribute them to a paisosed state of the blood (unemia), or to an anomic state of the brain through some source of exhaustion, as protracted comiting or diarrhon. Yet it is remarkable that some severe cases of nephritis in children, with an enormous escape of albamon from the system, are not accompanied by headache, or cerobral symptoms of any kind. If they are present, and the head is bot or painful, cold lotious may be applied, or a mustard position to the maps of the neck will be serviceable. Brounds of potassium or chloral may be needed to calm the cerebral irritation, and a free action on the bowels and kidneys must be kept up, so that the mortid products may be gradually eliminated from the circulation.

Lectures on Bright's Disease, 1873, p. 123.

^{1 —} I offer for your practical guidance this rate of tremment; when such symptoms as benducks, deligious, convulcions, or your use the results of arguain, give projection descip, and if the result disease by wate, and therefore probably number, you was meant will often be completely excessful. On the other hand, when you have seen.

Inflammatory complications, as pleurisy, pericarditis, broachitis, and peritonitis, must be treated on general principles, always remembering that the kidney disorder is the cause of the evil. Disphoreties and local applications, with careful regulation of the dist, are the remedies to be relied upon.

When the sente stage has passed, and there is passive congestion of the kidney, our treatment must undergo considerable change. Of all remedies, none are equal to small doses of perchloride of mercury, combined with the fineture of perchloride of larg, when every trace of blood has disappeared from the arine, and there is sufficient albumen to justify the opinion that renal congestion is present. I have known epithelial and fibrinous casts to be facilitated in their escape from the convoluted tubules of the Vidney, when these remedies have been continued for weeks, and the amount of albumen to undergo a marvellous diminution. When the evidences of general debility and amenia are nost prominent, the perchloride of mercury should be withdrawn, and the iron given plone. In some cases, the vinum ferri, or the scetate of iron, may be ordered according to the discretion of the practitioner, and if there is a deficiency of renal secretion, the bitartrate or the acetate of potash may be added.

160

talestore that the like brain-orangeous are consequent on perched homorrhage, or embelian, or threshold, he very crutions in the on of purpointes, which may greatly increase the patient's discuss and exhaustion, while they can do links to improve his condition. In inflammatory afteriors of the brain and its membranes, perguinter see when model, but has frequently and strikingly to then when cerebral symptoms are the reserved grazults."— Lestons on Dright's Discuss, by G. Johnson, M.D. F.E.S., 1875, p. 138.

CHAPTER XXIV (continued).

DISEASES OF THE REDUCEYS AND UNINARY ORGANS.

Corneyco Denguanavers: Navigaria: Sensition follows on seem other give might four or exposers is call – May be associated with (1) the force while bibliog. (2) the self-generalize bibliog. Symptoms of the discounted the began white bibliog.—Character of the wine.—Albemen occasionally about it conferred come.—One-bisloss to be flower from a micromopic construction of the order.—South red granular bibliograms in only (6)—Symptoms and mortist exposuration. On the remains observed if character is many bidrops.—Nature and crosss.—Sinte of the arises in .—Treatment of character displice discounts to the different speeches of the affection.

Curcon: response represents a reny rare disease in children; it may be the consequence of an neutr attack after searled fever, or exposure to cold, but in by far the greater number of instances it croops on slowly, and belongs to adult life. The course it follows and the symptoms it presents in children, are in all respects like the same disease in the adult. If the neutr stage does not pass away completely, and any inflammation remains belied, the urinary tubules become plugged with a fibrinous or explatine material, which interrupts the circulation through the gland, and by favoring a state of habitual congestion, renders the chances of recovery less promising.

After an attack of armie Bright's discuse (newle despansation as pleads), when the constitutional symptoms have improved, and the arms remains persistently alternisees, the patient is expect to a return of the disorder from cold, or errors in diet, resewing result congestion, and paving the way for incumble degeneration. This chronic form of disease may be associated with (1) the large

ickite hidney 1 (2) the red grandur kidney.

It appears that we may have disease of the kidneys communing in (1) the epithelial living of the totales; (2) in the flores torue; (3) in the bloodecode. The symptoms and morbid appearances are characteristic of each variety to a great extent, and ought to be carefully studied in their clinical history and pathological bearings. When the urinary totales are inflamed and irritated by the passage of a specific poison through them, as in scarlet force; they take on an excess of cell growth, and, as exudation proceeds from the congreted resouls, the kidney increases in volume, and become large and smooth. The capsule peaks off readily (large with bidney). If the disease is not arrested, or cored, the morbid altern-

tions continue, and the mischief extends to the intertubular structure, at the same time the growth of fibroid tissue begins, which may sad in contraction and granulation. The kidneys are reduced in size to one-half, especially in the cortical part, and the surface instead of being smooth is irregular and granulated. They are firm and fibrous, and the capsule thickened and adherent. The depressions and granulations are produced by the contraction of the fibrous tissue between the tubes (granular hidney—circlivit of the hidney).

The large white kidney is the sequel of an neute attack of nephritis, particularly after scarlet fever, or exposure to cold. The dropsy and ordens, if present during any time of the scate affection, pass off more or loss completely, leaving the state of the urine to tell the mischief that has been inflicted upon the resul organs. The albuminusia may continue for meaths, or even years, before symptoms of degeneration cases; or, indeed, at a time when the general health is in no way deranged. This, however, will greatly depend on the amount of albumen in the urine; if there is only a more cloudiness or epalescence in the secretion, the health may be unimpaired, and the patient perform the usual duties of life without suffering any inecurvaience, but a copious precipitate cannot continue very long without the liability of a return of dropsy and inflammatory complications. The discuse sometimes commences as a chronic discover.

The general symptoms of shrowle disease with a large schitchidary when pronounced, are a pale and pasty face, and droppy. There is loss of appetite and nauses, and the bowels and stemach are easily deranged, distribute and vomiting being very common. In the case of a girl under my care in 1876, the produce albuminaria was attended on three or four occasions with severe epistaxis, preceded by frontal hendache. Troublesome cough, from congration of the lungs and bronchial irritation, often prove extremely inveterate, whilst pericarditis, and serous effusion into one or both pleural sucs is not uncommon. Cerebral symptoms from unumin, and hamorrhages and extravasations of blood, more especially belong to the granular form of the complaint.

The urine is generally pale and of seemal specific gravity; as the disease proceeds, a microscopical examination detects granular and hyuline casts. The variability in the amount of albumen in the urine from time to time is just one of those circumstances which requires especial notice and attention. The patient, to whom I have alloaded, presented a good example of this when the chronic stage was established. There were days when the albamen was so small in quantity that the usine revealed on careful examination a more trace, and I had my doubts whether it was present at all; but when the usine was allowed to stand a few hours, after exceptilly employing the usual tests, its presence could invariably be verified. I can only connect this temporary decrease of alloamen to some mysterious process of digestion.* In many cases of alloaminaria the albumen is present in the urine chiefly, indeed, in many cases solely, during the period of digestion; just as in some cases of diabates the sugar is found in the urine mainly, and sometimes only, during digestion.

A case of albunúnuria is described in an infant seven weeks eld. It was born healthy, but soon after birth suffered from consunt vomiting. There was no history of scarlating or measles, and so evidence of disease in the thorax or abdomen; indeed, the child lay listlessly in any position in which it was placed, and apparently suffered no pain whatever. The nrine was "almost like pure water, and containing sufficient allounce to make a deposit of some height in the test-tube." Enucuation followed, and death took place at the end of a month. As the kidneys only presented some spots of congestion, the case was considered as one of albaminuria from imperfect digretion and assimilation of the albuminous constituents of the food." In other cases alloanen is never present in the urine except after severe exercise. The question may, however, he asked: Is albumon in such a case as this ever entirely absent from the urine? Dr. Roberts relates the case of n girl, ast 8, who came under his care in April, 1864. She had general amsurea after scarlet fever four months previously. There was excessive pallor, shortness of breath, and a juffy, pasty face, The urine was sounty and high-colored, but not a trace of allower or tube-east could be found. She died four works after admission. On a post-mortem examination, "the Edwar were good examples of the 'smooth, white Bright's kidney." They were slightly en-

Temporary albanisms may arise from indigentible unlider of food, as now binds of cheere, shellifold, earlier metals, etc. Nervous recitament and montal metion will also give rise to it.—Dr. Barbara, On Deopey, 1990, p. 200.

² Sol the remarks on International Afternaturality p. 253.

^{† &}quot;Afficiantization is a child seven weeks abil" by G. F. Helm, E.A., F.H.C.S.; Lincot, Jun. 19th, 1969, p. 85.

larged, and the capsule peoled off readily. The surface was depressed here and there, and atrophy had commerced."

There are some points worth considering here in reference to the microscopical character of the urine. In the earliest stages it is travely altered, being, as we have before mentioned, of normal micr and specific gravity, but more or less albuminous. When death occurs before fatty casts and cells are detected, the kidneys are in the first stage of degeneration (trage white smooth). When small bysline and oily casts and cells appear in the urine, there is a process of strophy (forty degeneration). When granular and large hysline casts appear, there is a further contraction of the kidney, or the disease is in the third stage (granular degeneration).

After death the kidneys are found: I. Lurge, white, and smooth.

2. The same appearance, with yellowish opaque specks on the surface (granular fat kidney), or large white kidney, with fatty degeneration. 3. Atrophy of the cortical portion, with an unerem granular surface (Johnson).

The small and granular kidney so far belongs to advancing years es to be hardly worth noticing under the diseases of early life. It is a chronic and insidious disease from the commencement, and although associated with the gonty diathesis more particularly, no cause can be assigned in a targe number of cases. It holds no relationship to tuberele whatever. Dr. Dickinson has seen the Some in a girl of 5. He mentions another case of a girl under the late Dr. Hillier who died at the age of 10, and one under Dr. Ogle, at St. George's Hospital, of a boy, who died at 11, "with granular degeneration traceable to searlatina." Dr. Dielcinson had two fatal cases under his own care at the respective ages of 12 and 14.) The disease has succeeded to scarlatina contracted many years previously. A case is related by Barthels; of a girl who at 10 years of age had ague, measles, and searlet fever, but no dropsy. At 18, after being in good health for eight years, she became affected with albuminusic retinitis; there was albumen, with small ligation casts in the urine, and hypertrophy of the left ventricle. Maddening headache and obstinate wealting succeeded to diminished uritary secretion. She became completely blind, and had

^{*} On Urinary and Renal Discuss, p. 406.

I Cyclopedia of the Pencilos of Medicine, by Dr. H. von Ziemssen, Discusse of the Ridney, vol. nr. p. 420.

five convulsions of an epileptic character in one day. To these symptoms succeeded twitchings of the muscles, prefuse diarrhou, and death from exhaustion. After death the kidners were found atrophied, and the surface mottled and covered with shallow its pressions; the substance of the organs was tough; rend arteries large; there was purplent peritoritis and alteration of the nuceum membrane at the lower end of the tleum; the brain was puls and firm; the left ventricle of the heart was hypertrophied.

The kidney in this disease is much reduced in weight, the surface is rough and irregular, and the capsule so thickened that it cannot be torn off the surface beneath without removing some of the tissue. Some of the crimary tubules are demaded of opitheliam, and others contain fibriness deposit. The urine, in granular disease of the kidney, contains a small quantity of albumen, and is copious and of low specific gravity; epithelial, granular, and hyaline costs are found under the microscope.

Dropsy is almost certainly absent, but there may be transient pufficess of the eyes and ankles. We often find dysputes or exertion from ordens of the pulmonary tissue or cardine change; and in these cases the face is sallow rather than white.

With these changes the heart becomes hypertrophied, and the arteries thickened. Simple cardiac hypertrophy is a common arescaparament of generalized linear of the killing; the morbid matters, not readily passing through the capillaries, raise the blood pressure in the arteries, and, an obstruction thus being created in the blood flow, the left ventricle hypertrophies. For a long time there may be no signs present except accordantion of the nortic second sound or reduplication, but not necessarily any marmur, unless the valves are discussed. Atheromatous change has been found in the mitral valve and north, associated with granular fibrosis of the kidney at the age of six." The muscular cont of the small arteries undergoes thickening, and even degenerative changes. The sphygrasgraph affords ample evidence of this in the characteristic tracing, and the finger placed on the pulse detects tension and hardness. This increased effort on the part of the heart and systemic arteries. causes both to become hypertrophied. As the heart increases in power the vessels loss their elasticity and become brittle, whilst the force with which the blood is driven through their channels. frequently leads to rupture and extravasations. The researches of

[&]quot; Dicklassa, specia, p. 412.

Sir William Gull and Dr. Sutton are in the direction of proving, that the view advanced by Dr. Johnson is unsupported by their experiments and investigations; they consider that blood charged with urinary excreta does not satisfactorily explain the cause of hypertrophy of the heart, and the arterial changes in the muscular coat of the smaller ressels. This change in the minute arteries is due to the formation of a "hyaline-filtroid" substance in the intertabular parts of the kidney, "and that, in fact, the muscular coat is often variously atrophied." The cardio-vascular changes are not consecutive to the renal mischief; they may be independent of it, and the contracted granular kidney forms only part of a general morbid condition. Those observers admit the frequent association between hypertrophy of the heart and renal degeneration, but at the same time they consider that this is no proof of any relation between them of enuse and effect. The large white kidney, the granular contracted kidney, and the lardsceom kidner have been found when the heart was free from hypertrophy. For further information on the subject I refer the reader to the paper of Sir William Gull and Dr. Sutton,"

The next form is that known as the brokenous or early library. It has also received the name of anyloid tidary. A waxlike natorial is found infiltrating the kidney, commencing in the mancular coat of the minute arteries; this imparts to the kidney a
smooth and anomic look. When the disease is far advanced, the
gland lesses all its smoothness, and becomes shrunken, uneven, and
puckered. On incising the surface, the natural structure is seen
to be much wasted, the cortex is bloodless, and the cones red,
whilst the whole organ is much more tough and hard. This discase is accordary and constitutional, not local. It consists primarily in a change in the composition of the blood, and secondarily
in the walls of the arteries, as well as all the organs of the body

which they apply.

The striking poculiarity of the morbid deposit is a deep brownreddish color, which it assumes on the addition of a weak solution of iodine.

The cruses of the disease are chronic suppuration from caries or

1 See Chapter XX, On Disease of the Liver, "Lurdscown or Amyland Disease of the Liver.

^{*} Med Cair. Trans. vol. is, 1972; Chronic Bright's Discuss with Contracted Killer (Americ-capillary Filocom).

nerrosis of hones, scrofulous absences, phth'sis, phronic bedsores, syphilis, etc.

The discuss is essentially chronic and most common in males. It is most frequent between 20 and 30. Dr. Dickinson has seen it in a child of 5, and he alludes to the case of a boy 21 years old, under Dr. Goe, who died from chronic abscesses in the thigh and pysmin." The discuss is recognized during life by a worn and eachestic look; by the copious secretion of albuminous urine; and by the presence of orderna and dropsy. The urine is abundant in the early stages, but as the complaint advances it becomes scenty, very albuminous, and of high specific gravity. "Cells resembling those of pus are excusionally found, either separate or aggregated round a cast. The tube-casts are usually hyaline, and do not yield a brown coloration with iodine. Epithelial casts are also sometimes seen."? They are sometimes granular, or they contain fatty epithelium (Green).

Treatment of Chronic Bright's Disease. - To aim at a cure or to give relief in this formidable complaint, we must bear in mind the course of the malady and its tendency towards a fatal termination; for in so doing we know what symptoms to expert, and how best to avert or relieve them when they threaten. The cause having been ascertained, we may learn how to approach the disease in lie milder forms with some chance of success. Is it the sequel of an neute attack, or a chronic insidious disease from the first? Is the constitution fairly good, or the health broken down! For on the issue of these questions our opinion may be in a great measure guided. In one case the tendency of the renal changes will be to cause cerebral trouble in the form of chronic headache, conficin of bless, and convulsions or come; in another case inflammatory complications of the serous cavities; in a third anasarea or dropsy: in a fourth derangement of the stomach and bowels is the chief evidence of the poisoned blood; in a fifth the changes fall chiefly on the systemic vessels, and the left ventricle of the heart, produring for a time no other indication of failing health than stupor and inactivity, nausea and capricious aportito, or occasional egistaxis or laymaturia.

If the chronic disease has succeeded to the soute variety of the affection, as after scarlet fever or exposure to cold, great care is

^{*} Mekinem, part 2, Albeminaria, 1877, p. 401.

[†] On Unitary and Resal Disease, by Dr. Roberts, 1876, p. 898.

required not to submit the patient to changes of temperature, or to an irregular diet, as acute renal congestion is rekindled on slight provocation. If there is chronic discuss of any bone or joint, and the alluminum appears to be dependent on these affections, then the source of such irritation should be removed if possible before the patient's strength is worn out, and the renal degeneration is too far advanced.

If there is local pain to any extent across the toins the patient should be put to bed and a lineed positive applied. If the arion is suched and contains renal blood-casts, it is advisable to make the child lie on the abdomen to lessen the renal congestion, and to give diments and fluid diet. In one case immediate relief followed the adoption of this simple method of treatment.

When the patient is well enough to be out of doors he should be warmly clothed with flaunch sext the skin, and the greatest care be taken to avoid sold. A residence at the senside is to be recommended, and moderate exercise may be taken if the disease is not so far advanced as to prevent it.

All treatment will be futile without the most rigid attention to diet, and this should consist chiefly of milk, or milk and water, if there is much albumen in the urine, and renal congration is present to any extent. Animal food should be prohibited under these circumstances, for if indulged in it will increase arterial tension, and derange the digestive functions. This is not become out by the experience of some writers, who consider that minual food should be given as soon as the stomach will bear it. "It is a most remarkable fact that the albumen in the urine decrease by the use of minual food, and increases again under a vegetable diet." But this testimony is quite at variance with my experience, as the case of E. S----, related at p. 257, very strikingly proves.

All stimulants should be prohibited, as they are apt to produce deleterious consequences. Children do not require them in health, and there is no disorder in which they would prove more injurious.

If anymin is a leading feature of the complaint, the liquor ferriperchloridi is a good humatic, and a safe discretic at the same time. When the urine is deficient in quantity, and there is any annurca from renal inadequacy, the efficient of the tineture of the perchloride is well spoken of in combination with the liquor ammonia-

^{*} Basham, On Dropsy, 1865, p. 267.

need that its beneficial influence becomes most apparent. It is a very simple preparation; a few drops of the tineture, according to the age of the patient, are added to a drachm of the liquor aumonite acetaris, previously acidulated with acetic aced." Another teritor on this subject also testifies to the same offset. "I have frequently combined with each does of the perchloride of iron ten grains of the hydrochlorate of ammonia; and I believe that this ammonic-chloride of troo is a useful preparation."

If there is any result congestion, the addition of small does of perchloride of mercury to the figure ferri perchloridi, as previously referred to under the acute affection, will be advisable. The syrup of the iodide of iron, the syrup of the phosphate of iron, or stud wine, in combination with cod-liver oil, are useful preparations in atransous subjects, and may be taken advantageously for reside together. However important it may be to improve the quality of the Idool in chronic Bright's disease by the exhibition of ferral gluous preparations, they cause in many instances so much lead-ache and constipation, that they cannot be given about for any length of time; if the headache is dependent on congestion rather than on anomia, they must be set aside for other remodies. The bowels ought to act once every day at least.

Sometimes the mineral acids—phosphoric, nitric, or hydrochloric
—are useful where the loss of alloumen is excessive, and there is
atomic dyspepsia. Gallie acid seems to be ineffectual in lessning
the drain of alloumen.

Dr. Lander Branton found that strychnia in doses of gr. 19th stopped the alliamon in a case of chronic and intermittent alliaminaria, but caused sickness and headache; in the same case parcreatic emuision stopped it at first, but afterwards it became werse than ever; quinine and sulphuric acid doubled the quantity in twenty-four bours. But the same authority speaks in the highest terms of arsenic, which acts "upon the secreting structures of the kidney . . . and appears also to possess a special affinity for opitholial structures." He gave Liq. Fowleri ugiij at mealtines and the albumen disappeared, reappearing when the arsenic was discontinual, and again arrosting the albumen when the remoty was resumed. The case in question was supposed by Dr. Branton to

^{*} Tinhan, On Thopay, 1881, p. 218.

[†] Lectures on English Discore, by G. Julius at M. D., 1872, p. 158.

be due to "imperfect digestion of albuminous substances, which were absorbed from the intestine, and excreted in the nrine in much the same way as white of egg would have been if the person had swallowed several raw eggs at once."

For any dropsical condition that may exist, a dose of the compound julian powder, with a little literatrate of potash, is a good and quickly acting operiont, which may be given once or twice a week in a little ten or plain water, early in the morning, but even this aperient must be employed with due consideration to the general strength.

If anssareous effusion is great, it may be necessary to puncture the extremities. The ordinary practice is to make one or two panetares through the subcutaneous tissue on the dorson of the not or call of the leg, from half an inch to an inch in length, and then to wrap the limb in hot moist flamed. I have repeatedly made a small peneture either on the dorsum of the foot or over rue or both ankles, and then wrapped the limb in dry flamel, changing it as often as it becomes very wet. I have never seen any local irritation or crysipelas follow this plan, though the drain of fluid in some cases has been enormous. Dr. Southey has recould the notes of a case of parenchymatons nephritis, in which the amearca was combated by drainage-tubes and small silver canulas. The advantages claimed were, that one puncture in each limb was sufficient, and that sores and orysipelas were not so likely to ensue; the canula could be kept in the same opening without inconvenience for forty-right hours, and when the instrument was withdrawn the orifice closed at once. Above all the patient is kept dry. Several pints of dropsical effusion may thus be safely and painlessly drained away in the course of one day, Dr. Souther found the same plan comilly advantageous in drawing away pleuritic effucions !

Direction are consetimes serviceable to assist in the removal of bropsical effusions. In some forms of the disease diuresis is profew enough to contraindicate their ase. They are infinitely less valuable than purgatives, which relieve the portal circulation and intestinal veins, by inducing watery secretion from the bowels. I have a great preference for digitalis, with acetate or citrate of petash, when an alkali is not objectionable.

^{*} Americ in Albuminuria, Practitioner, June, 1877, p. 432 † Clin. Trans., vol. x, 1877, p. 2 | Det., vol. nii, 1879.

Bronchial and dyspeptic symptoms require no special consideration; they must be treated according to the circumstances of each particular case, remembering that the strength of the patient is to be earefully husbanded, and that mercury and antimony, if occasionally required, are soldom necessary.

If urremic symptoms threaten, the action of the skin and kidners must be encouraged. The prosoned and watery state of the blood will seldom admit of venesection or any kind of depletion.

An occasional warm bath is an excellent dispheretic, by promoting the action of the skin, and increasing the secretion of urine at the same time. The skin becomes supple under its use, and a general amelioration in the patient's condition takes place. I have known bendache relieved when the temperature of the bath has not exceeded 98°, but if much higher, and there is no free aventing, headache, capillary engorgement of the face, and other distressing symptoms may ensue.

Finally, we may repeat that warm clothing, thick boots, care against cold, especially in the evenings, and a seaside residence ought to be rigidly enforced.

CHAPTER XXIV (continued).

DESCRISES OF THE KIDNEYS AND PRINARY ORGANS.

Descrit - Resal Concernion and Carcell - Lermann - Symptoms of Some in the Kinger and Relation - Ocarcell - Hangauria - Terraise of the Kinger - Hangauria - Terraise of the Kinger - Hangauria - Description - Legente - Legente - Symptoms and Processal.

- Symptoms and Processal.

Drauma—Renol Concretions and Calculi,—Calculous disorders are very common in early life, from the liability of the digentre functions when deranged to cause irritation in the arisary passages. The imperfect assimilation of the nitrogenous principles of fool checks their downward metamorphosis to area, so that a quantity of intermediate products are formed; these products are either insoluble, or, at least, irritating to the genito-arisary organs.

Lithing's is recognized by pain and weight about the loins, and difficulty in voiding urine, which is scanty and high-colored; it becomes turbid on cooling, and has a strong sickly oder. The commonest form of gravel consists of urate of ammonia, or free aric acid, which falls to the bottom of the vessel on standing like brickdust. The digestive functions are deranged, the tongue being forred, the appetite excessive, and the bowels coetive. The child is restless and feverish at night, and loss energy and activity. The white or pink those of the urates depends upon the amount of coloring matter in the urine. "In young children the 'milky nrine,' which alarms mothers, is thus to a deposit of peculiarly white urates." The pink or brickdust deposit, only risible after the urine has cooled, and readily dissolved by heat, consists of the amorphous urate of ammonia colored with purporin. The milky sediment, which exists as a deposit before the urine has cooled, in formed of the crystals of urate of soda.

When a careful section of the kidneys is made, yellowish or brownish strice may be seen running towards the base of the pyramids. This appears to be a post-mortem change arising from the precipitation of the wrates into the wriniferous tubes. When it occurs during life it may prove the commencement of those changes which lead to gravel or calculus, blocking up the wriniferous tubes, and finally causing them to become impervious, or the concretions escape into the privis of the kidney, where they may be seen in large numbers after death.

The symptoms of stone in the kidney, or of the descent of a calculus from the kidney to the bladder, are less marked in childen than in adults. There is febrile disturbance, and pain and difficulty in passing water, with localized pain and tenderness over one lois. In severe cases, there is faintness and vomiting, and the skin is belowed with a classical weat. Uric seid calculi have been seen in the polyis of the kidney of an infant. The occurrence of colic in children of three or four years old is often attended with nric acid gravel (West). It must always be been

^{*} Unite to the Examination of the Urine, by Dr. Wickbern Legg. 2d edition, 1872, p. 48.

^{2.} In the urine of children it is very frequently east with in the form of small spherical globales cosy like the crystals of carbonate of line love horses' soint; and three sometimes somer in the adult."—Line and Urinery Deposit, by Dv. Reule, 1991, p. 253.

I "In inlines dying within Kerty-night hours of their high, such strin are almost bremadly found (Vireleas); they have also been found in still-bern infinite, which have sever respired (Hoogeway and Martin)."—On Uniong and Kond Discore, by Dr. Roberts, 3d edition, 1870, p. 477.

I "Dr. Debose d'Estries gives an account of a child at Connexoville, bora of gony

in mind that it is most difficult to elicit symptoms of localized pain in children.

The treatment of dynamic and sole and grand, when sever, consists in the employment of warm baths at bedtime which relieve the pain of mictarition and encourage displacesis. If there is reason to think from the local and recurrent pain that a courrection has formed in the kidney, hot positives to the loins will be advisable. The bowels must be kept fully open, and for this purpose there is nothing better than a full dose of castor oil. After this a mixture of liquor potasse and theoture of hypocyamus will lessen the acidity of the prine, and promote its free discharge. The dist should be sparing and antimulating, and should consist of milk and water, burley-water, and thin arrowyout. No animal food should be given whatever till the prine has assumed a healthy state, and pain and irritation have passed away. The waters of Carlahad and Vichy are very useful.

In children, colredi and arinary sofistents usually consist of urates, hence the alkaline carbonates are very serviceable, and they may be persevered with to great advantage. Children who have had rheumatism sometimes suffer from uric sold in the urine, and in such cases the diathesis will require careful attention.

When a stone has formed, the child must be landed over to the surgeon. The symptoms of abuse in the Madder in children are the same as in the abult—frequent desire to pass water, which is voided with printial efforts, and is sometimes mixed with blood; occasional stoppage of the stream, and a sore and clongated prepure from the child's hands being constantly applied to it. I'velapson and, accompanied with marked dynaria, is often the first symptom of calculus in children.

Calculi, though frequent in boys, are very earely found in fertale children. Hence, when morbid vesical symptoms occur in little girls, the probability of the presence of a stone in the hisdor must not be overlooked on account of its rarity. In the autumn

parents, which had real nephritic its at a farmight old. The mather, a point women, the arrivals years old, who had been nathing from trie gravel for four pare, but drawing for pregnancy, there is of nephritic colic; nevertheless, the shift was been in time and in good condition, but a fortaight after in high it had seed orginals for, countries, weithing, and complaining chiefly when the hims were model. The fire entired by the meiosion of under thick send. They eccursed every six weith "

A Few Hards on the Course of Grand, Practitioner, June, 1877.

of 1877 a girl, nine years of age, exme under my care in the Samaritan Hospital. Her mother stated that she had been subject since forth to incontinence of orine, and for more than six months before admission she suffered from dysuria, with constant desire to pass water. On the day of admission the labin were swollen, and the clitoris was large and tender. A few excrescences, prither vascular nor painful, existed around the meatur arinarius. The arine contained a trace of albumen, and there was a scanty deposit of pus-cells. Suspecting the presence of a calculus, I asked my colleague, Mr. Alban Doran, to sound the patient under chloroform. He discovered a large stone, and two days later removed it through the methra, which he enlarged by means of the dilator, invented by the late Professor Simon, of Hestelberg. The stone weighed 21 drachus, and consisted of a purleus of uric acid, coated with exainte of lime. The patient was enabled to retain her urine and to pass it at will the following day. She made a good and rapid recovery,

Within a month after this patient was discharged, a delicate girl of ten was admitted, also suffering from incontinence of urine and occasional dysoria. There was a distinct history of calculus in the family, her maternal uncle having been operated on for stone when a youth. A sound was introduced into the bladder under chloroform, but no calculus could be detected. The mucous membrane of the bladder was rough at one or two points. The inquinal and the whole line of like and lumbar glands were much colarged, but the alsoeminal walls were flattened, and none of the solid viscara had increased in size. On examining her urine two days after the sounding it presented many of the qualities it did on admission; it was very soid, and deposited a large amount of mucha. Under the microscope, a great number of crystals of onalite of lime were detected. She recovered completely under rost and antistrumous remodies.

Dr. W. Roberts* and others have shown that although are larger is most frequent in pervous and debilitated young people, it is not accompanied with definite symptoms, since in many cases it may exist to such an extent as to produce the characteristic mulberry calculus, without any constitutional symptoms, until the stone has machanically caused vesical irritation.

Hemotorio or homorrhage from the kidneys in children may be

met with in tuberculosis, scarlatina, purpura, and some other discases in which the blood has undergone changes in its composition. A case of neute hematuria is recorded in a girl of nine, in which sudden hemorrhage followed the disappearance of severe postular occuma on the face and body, of two years' duration. I have given details of a very interesting case of "Paroxysmal or intermittent hematuria in a young child, following supposed injury."! The treatment must be in accordance with the disease which has originated the symptoms. Gallio acid in five-grain dotes, three times a day, will be found beneficial, and if there is anamia, the timeture of the perchloride of Iran is a good stypile and direction at the same time. Quinine may be sometimes prescribed with advantage. If there is any evidences of renal congestion, rest in bod and a nilk dire will be necessary.

This rele of the hidney in seen in cases of general tuberculons, one kidney being generally affected. The organ is increased in size, and converted into a soft, cheesy, yellow mass. Any treatment is unsatisfactory.

Conver of the Gidney is a rare disease, and when present, is of the medullary character.; I have had no experience of the affection, but authors describe the symptoms as beginning with pain in the region of the kidney, frequent micturition, and the presence of blood and albumen in the urine. It is extremely doubtful whother career-cells have been seen in the urine. "The most important symptom is a generally uneven, redulated, immovable turnor, cometimes as large as a child's head, reaching from the false ribs to the crost of the ilium, and inwards to the vertebral column, and occupying a considerable part of the abdoninal cavity." (Steiner & The children become cachestic and sallow, and finally die exhausted. Mr. Speneer Wells has recorded a most interesting case of 10th toxest of the right history in a girl only four years of age. "The diagonals in this case was made without much diffculty, although the urios was quite normal. The growth was extremely rapid, hardly six months from its commencement to its fatal termination, when the diseased mass weighed between 16

[&]quot;Brit. Med. Journ., 1878, vol. 11, p. 877. + The Lancet, vol. 11, 1810, p. 530.

^{4 &}quot;In the Children's Hospital at Prague in 100,000 cases is was only non-but fance."—Steiner to Discover at Children, by Litmon Tain, 1974, p. 279.

f "In 15 children its average weight was \$2 Ma.; the smallest was 1 ft. 9 m, and the largest 31 Ma,"—On Urinary and Road Discouol, by Dr. W. Bobarts, 1976, p. 525.

and 17 lbs. The tumor occupied the whole of the right side of the abdones, bulging backwards in the right loin. It was uniformly clastic, but no fluctuation could be detected. The intestines were pushed downwards, and to the left side. The rapid growth, and the absence of fluctuation, were, of course, strongly against the opinion that the tumor was ovarian; while the rarity of ovarian disease in young children, and the comparative frequency of renal enceptudoid, ted to a diagnosis which was confirmed by a poneture with a fine exploring needle. A few drops of roddish serum were oltained, containing nucleated rolls of various size and shape. I sent the child home, with a note to Dr. Williamson, of Nantwich, expressing my opinion that the tumor was a mass of soft cancer, and that the right kidner was the most probable seat of the discase. This proved to be correct. Dr. Williamson sent me the specimen, and I exhibited it at the Pathological Society in Decemher, 1862. The whole kidner was infiltrated with encephaloid. Alabough so enormously enlarged, the shape of a portual kidney was distinctly preserved. Its surface was soft and elastic in some spots giving a sense of despecated fluctuation, but no syst was found, nor were there any marks of suppuration or homograps. Colls of small intestine adhered to its inner and under surface, The ureter was completely oscluded by the pressure of the tumor. The left kidney was quite healthy. Thus the normal condition of the urine was explained. The diseased kidney added nothing to the contents of the bladder, and the healthy kidney supplied only normal urine."+

Hydroxephresis — Dropsy of the Kidney. —This disorder is caused by an obstruction to the escape of urino from the kidney. The pulsis of the kidney becomes dilated into a peach or bag, and the renal substance atrophied or absorbed. Sometimes it is divided into smaller compartments or cavities. The tumor may attain enornous dimensions, and fill the abdomen as a soft fluctuating mass. In women it has been mistaken for an ovarian cyst, and topped under that impression. One or both kidneys may be affected.

"Of 52 cases collected by me the hydronephrosis was confined to one kidney in 32 instances, and affected both (double hydronephrosis) in 20 cases. When the hydronephrosis was single the

^{*} Truss, Path, Soc., vol. xiv., p. 173.

[†] Diseases of the Oraries, 1872, p. 201.

² See Chap. XXVI.

right side was more frequently affected than the left (19 right and 18 left)."* Of those 52 cases "there existed congenital malformation in 20 cases, affecting the kidneys, the ureter, and the resal artery...... In 13 sext of the 20 congenital cases the hydronphresis was double, that is, it affected both kidneys. Two of these perished still-born, one lived six hours, one thirty, and one thirtysix, whilst one died twenty days, and another between three and four months, after birth."

The contents of these cysts consists of untery urine, uric arid, and the earthy salts, but blood, pus, and epithelium may be also present. Death may occur suddenly from uromia. In some race of congenital hydronephrosis ures is absent. A very interesting case is recorded by Mr. Henry Morris to prove that urine is feely secreted during intrauterine life, and that a considerable quantity which the bladder and wreters amont hold is passed into the acc of the amonom, in which the child floats. Urea appears to be in very small proportion (5 in 1000).

Hydron-phrach is found to be caused by the impaction of a stone or calculus in the oreter, which causes inflammation and centraction; an imperforate orethra is another cause. A priving growth, by compressing the wreter, may prevent the secape of the urine. In some obscure cases no mechanical cause can be ascertained to account for the condition.

The symptoms depend on the size of the tensor and the pressure it exerts on surrounding organs. The mond situation of the tensor is in the lumbar region, extending forward to the umbilious and downwards to the fline region. The tumor is soft and fluctuating it is sometimes felt distinctly lobalated, and if of large size there is dyspaces, and the child cannot lie down without difficulty. The colon generally lies in front of the tumor. "There is one peculiarity which is pathognomenic when present, namely, the endden diminution or disappearance of the swelling coincidently with the sudden discharge of a large quantity of urine. This sign is not always available, but it is sufficiently frequently met with to give it an important diagnostic value."

When the symptoms arise from the impaction of a calculus,

^{*} Repail and Crimicy Discusse, by Dr. Roberts, 3d adit., 1870, p. 487.

attacks of pephritic role and vomiting are not uncommon, with
pas and even blood in the arine. If both kidneys are affected,
then the elimination of uses is imperfect, and symptoms of uromis
may be looked for. Should the disease be caused by a rend calculas it may be distodged, and, the sac emptying itself, the symptoms pass away, the sac shrivelling up and causing no further
trouble. Peritoritis, septlemmia, or suppuration in the tumor, followed by heetic, may onsee. Impaired health and chronic tuboronlosis have also followed.

Treathcost.-A milk and fluid diet is preferable to much amount fool, as it is important to keep the urine free and to avoid the assumulation of focal matter in the lowels. When there is conslipation a warm-water enema, or a mild non-irritating aperient, will be called for. In the case of a little girl under Dr. Roberts's ears, friction and shampooing the tumor resulted in the escape of a large quantity of urine, and the swelling subsided. Other cases are recorded where the tumor has suddenly disappeared after a profuse discharge of urine through the ureter and bladder. If this does not occur, and the patient's rost is broken from pain and want of sleep, tapping may be had recourse to as a means of temporary relief. In October, 1879, a girl seven years of age was adnotted under my care into the Dorsic Street Branch of the Sanaritan Hospital suffering from abdominal tumor, which had been known to exist since she was two years old. The case was seen by my colleagues and variously diagnosed as hydatid, ovarian, and renal. Mr. Knowsley Thornton, holding the latter opinion, adrised and performed exploratory and antisoptic tapping, and drew of six and a half plats of slightly albuminous urine. The erst rediled, and, the diagnosis being now certain, Mr. Thornton removed the cyst by laparotomy on January 2d, 1880, securing the reval vessels with fine carbolized silk, and using all details of Lister's method. Some congestion of the other kidney, with hounsturia, followed the operation, but passed off in a few hours, and the child recovered rapidly, and four months afterwards was in perfect health. The cyst was shown as a fresh specimen at the Pathological Society, January 6th, the child at a meeting of the Royal Medical and Chirorgical Society, March 9th, 1880, when reparectomy was under discussion, and full dotalls have been published by Mr. Thornton jointly with myself."

^{*} The Lauret, vol. i, 1880, p. 870.

Energie (incontinence of urine). This common disease in shill dren is generally difficult to cure, and the closest investigation frequently fails to discover the true cause. It is met with in the progress of discuse of the bindder and brain, and from deficient power in the tone of the bludder and sphincter, in weakly and strumous subjects. "We can sometimes trace the affection to spinal irritation; and the worst case of the disease I ever see was in a girl affected with diseased spine," It may originate from guetro-intestinal disonler, ascarides in the rectum, and an excess of uric peld in the prine. When these sources of irritation are removed the patient gets well. But incontinence of uring, among children in too many instances, appears to arise from no mechanical or inflammatory condition of the bladder or kidney, and from no unhealthy state of the urine. We know that the child wels the bed, but neither the purents nor the physician can always assign any reason for it. A long propuce would seem to be a frequent cause. A very obstinate case under my care, which had resisted all drugs, was sured on its removal. Children who are pat to led without emptying the bladder, often wet the led at night, and when the habit is coree established, it is difficult to overcome. In some children the absence of control over the bialder occurs only at night, and in others during the dartime also: in some cases there is almost a constant dribbling, and the rhod is not and experienced, whilst in other cases the desire to pass water is very frequent, and he cannot hold it for a moment when once the desire to pass it has commenced. Boys suffer far more frequently than girls. It may be again urged that the condition of the urine may increase its irritating qualities, especially acid conditions. In such cases, a comparatively small quantity of urine in the bindder may excite reflexly the relexation of the sphinnters.

Incontinence of prine commonly depends upon an absormal condition of the bladder centres situated in the lumbar portion of the cord.

In normal micrarition, the sensation of falness in the bladder is received by the centre in the cord, until it excites an effectal impulse to the sphineter, which relaxes and permits the contents of the bladder to escape. In early infancy this does not excite consciousness; then the micrarition is involuntary, and parely

^{*} Helises's Sergical Transport of Children's Diseases, 1898, p. 581.

refex. About the period of the completion of the first dentition, or even earlier, a child ordinarily becomes conscious of the call to roid urine, and intimates the desire to its nurse. The relations of the call to consciousness have become established. These relations never become lost again ordinarily, except in very advanced life, or in disease of the spinal cord. Under other circumstances the relations of this call to consciousness do not become perfectly established. In the majority of cases of nontarnal incontinence, during the period of wakefulness, the little patient in conscious of the call, but during sleep the reflex action goes on without exciting consciousness. In more aggravated cases the call does not excite the attention, and the incontinence occurs during the waking state, as well as during sleep.

Programis.—This is hopeful, for as the child grows older be gains strength. Incontinence of urine usually ceases at puberty, when the spinal centres become perfectly developed. The disease is never fatal.

Treatment.—From what has been written concerning the causes of enurseis, the treatment will have to be adopted accordingly. The patient should lie on a hard bad, and strict attention be poid to bygienic rules. As bedtime approaches, the quantity of fluid should be limited, and two or three hours after falling asleep the child should be awakened to pass water, and the same thing should be repeated during the night, that the bladder may not get too fail. He should be prevented from lying on his back, and for this purpose a handkerchief tied round the waist, with a knot over the ajme.

If the urine is high-ecolored and there are urates, it must be put into a healthy state, but if it is clear and throws down no deposit, the extract of beliadoons (gr. § to gr. §) three times a day is a drug we ought to employ. "It appears generally admitted that of all specific means the administration of beliadoons is the most effectual, and such is certainly my experience. I begin with §th of a grain of the extract three times a day, or a smaller quantity in very young children, and gradually increase the quantity until the fances and the pupil become affected. If the courses is not materially relieved by the time the fances become day and the pupil enlarged, I leave off the drug; but if there is a material improvement, a few days' perseverance will usually ours the disease for a time. I believe that it is liable to recur, as I have seen several cases of relapse. They are, however, under the immediate central of the drug, and are, therefore, of no very serious consequence."

In belladonna poisoning there is paraly the retention of urise, consequently in these cases of hyperesthesia of the bladder centres belladonna is useful.) In those cases where no abnormal source of irritation can be discovered it is well to give belladonna. In many cases this drug will effect a cure, but it should be given in full doses, and all young creatures, including human beings, bear conparatively larger doses of this agent than are required in the case of adults. "I have been obliged to give as much as Sass or even Sej of the fineture before success was attained." In many case it is well to add bromide of potassium to the belieforms.

If the condition seems to depend on debility, the tincture of the perchloride of iron, with or without structuria, will be found of service-five minims in a little water three times a day has often proved of great benefit in my bands. The mineral acids, too, are sometimes serviceable. Cold sponging to the loan and lower part of the back in the early morning are useful measures, and in very obstinate cases a blister to the sacrum. "Another local application, which is very energetic, and in obstinate cases ought cortainly to be employed, is the canterization of the neck of the bladder. Either the stick-caustic should be used, or a solution of ten grains or even more to the onnce. I prefer the former. But it is a very painful application and not free from danger, and should nover be employed till after the failure of general treatment." I have applied to the orethra, a solution of nitrate of silver Diad \$1, with very encouraging results. The patient, a nervous timid girl, but years of age, had suffered from inequationee of urine from birth, and the treatment hitherto employed had been menoceaful. The incontinence took place during the night, as well as the day, and the mother said "her child's clothes were always wet." I used a small aterine sound, and twisted round the top of it a piece of cotton-wool, well saturated with the solution. This was passed along the urethra to the neck of the bladder, and then quickly withdrawn. The application cancel no pain at the time, nor my subsequent inconvenience. At the end of a week, the patient had

[&]quot; Helstein ern cit., p. 1833.

¹ Holmes, op. vir., p. 184.

only wetted the bed once; at the termination of a fortuight, twice; and on both these excasions the incontinence was recturnal. I should state that as the orine was high-ecored and rather acid, I prentibed a mixture of belladonna and bicarbonate of patach, but the good effects were, I believe, largely attributable to the constic application, as the child had been under the care of several medical men, who had, no doubt, employed the small remedies.

In some cases of imperfect development of the cerebro-spinal system, this incontinence of urine is best treated by strychnia, a well-known stimulant to the spinal centres; in other cases there is a hyperasthesia of the bladder centres in the cord, and then a solutive like brounde of potassium is indicated; in some cases, other different sensations than these of a full bladder are received by this centre, and under what may be called a misconception, the efferent impulse is sent off to the sphincter to relax, and the contents of the bladder escape. In such case, careful search for every possible source of such irritation must be instituted, and, if possible, be found and removed. Without that, all treatment is fatile.

According to Dr. Herbert Tibbits, incontinence of nrine in children has yielded to faradization after every other sort of treatment had failed. "One sponge should be applied over the symphysis publis, and the other to the sacrum and perimeum alternately."

Sometimes sourced arises from a long prepare, and when this is the case there is nothing to do but to remove it. A boy, aged six years, came under my care in 1871, suffering from incontinence, which was perpetually troubling him during the day, but not at night. The prepare was very long, and the child perpetually put his hands to it, which kept up the irritation. The tincture of the perchloride of iron was given without roller. Hydrats of chloral, in five-grain doses every night at builtime, caused temperary improvement, but he soon grew worse than ever. Large doses of belladown kept the disease in check for three weeks, and then the symptoms returned with their former severity. The removal of the prepace completely cured him.

A chronic case of incontinence of urine is recorded by Mr. Teevan, in which a perfect cure was brought about by an operation.

† A boy, 12 years of age, had suffered from necturnal incon-

^{*} A Hamilton's of Medical and Surgical Electricity, 1977, p. 215.

[#] Practitioner, October Ist, 1876.

tinence from birth, and all medical treatment, including iron and belladonm, had been unavailing. On the 11th of February, 1876. when Mr. Teoron saw him first, the wrethral crifico was "not much bagger than a pin-bole," and there was, in addition, "a small blind internal fistula situated just above the sphincter." The sphincter was divided, and the floor of the meatus externus incised. Six weeks afterwards the cure was complete and permanent.

Acute could's is sometimes met with in children either from injury, or the irritation of stone in the bladder. It is also said to arise from cold, and to occur during the course of febrile affections. The mucous membrane of the bladder is injected and swollen, and pours out considerable secretion. In the chronic form, mucus and pus are freely poured out. The symptoms are straining in posting water, followed by a few drops sometimes mixed with blood; pain over the pubis and weight in the perineum. In a case of simple sente cystitis which came under my notice in November. 1876, the desire to pass urine was frequent, and very painful. The patient was a girl ten yours of age, and no cause could be discovered to produce it. There was no indication of stone or other mechanical cause. The arine was neveralbuminous, but frequently high colored and turbid, and this was the only explanation that could be offered. Under the influence of rest in bed, and a milk dies, with a mixture of citrate of potash, the symptoms passed off in about a fortnight, the urine never becoming ammonized or alkaline.

Transment.-This consists in confinement to bed, and the suployment of warm hip-baths at bedtime, if mietarition is frequest and painful. A linsood-meal poultice should be employed over the loins, or lower part of the abdomen, if there is much pain. A demulcent mixture of mucilage and liquor potassic, with or without opium," is useful to allay pain and irritation which the acid urine excites. In some cases, tincture of belladonna with citrate of potash is even more efficacious. As a mild and efficient purgative there is nothing better than castor oil. The diet must be simple and no stimulants of any kind should be given. Milk and

⁺ Farmala 45 :

R: Lisywa, pittane, Liquie opli rol. Liquer, epii ml., Macilig...

water, or milk in acdn-water, are the best forms of mourishment.
If milk is strongly objected to, then weak yeal or chicken broth,
and barloy-water must be substituted. In this respect, the diet
and treatment generally are closely akin to that recommended for
the uric acid diathesis.

CHAPTER XXIV (contravel).

DISEASES OF THE RIDSEYS AND DEINARY ORGANS.

District: Ferida of 1 Districts Stricture: Symptom—Chara-Ton for more path trias—Pethology—Propose—Territorial, 2, Districts (Secretary, on Sturies Districts), Symptom—Chara-Pathology—Transcal.

Diagrams untarrus is recognized by a large increase in the prinary secretion, owing to the presence of sugar. The complaint is not frequent in adults, and in children it is exceedingly rare, particularly under five years of age. It is not aliaded to by Tanter, or Meigs and Pepper, Vogel, or Lewis Smith. Dr. West mentions one case as having come under his observation, in a little girl three and a half years of age, whose breaker at two years, and whose sister at two and a half years, died of the same disease. Out of a total of nearly 700 cases, Dr. Prout only saw one instance in a shild of five, and about a dozen cases between eight and twenty years of age, four of whom were females. Thr. W. Reberts men with it in a boy of three years, and he mentions the singular fact that as many as ten deaths from diabetes under the age of one year are recorded in the Registrar-General's Report for 1851–1860.

Symptons.—These are gradual in their easet, the disease being generally of some weeks, or even months duration before it is discovered. Failing strength and gradual loss of flesh, notwithstanding an excessive appetite, excite suspicion that the patient is going wrong. Then the frequent calls to pass urine in immoderate quantities, and the insatiable thirst scen clear up the nature of the malady. It is worthy of notice that there may be urgent thirst before the renal secretion is increased. The urine is of a light

^{*} West, us the Excesse of Infancy and Childhood, 1839, p. 654.

¹ Pross, on Stemark and Benal Renewater, 1948, 5th edit., p. 26.

¹ On Urimey and Rosal Discours, 1976, p. 221.

strau-color, and has the odor of neu-moun hay; it is more or less specific gravity, reaching 1030 to 1050, or even 1000. In this respect it differs from alluminous urine, and that of dialetes insipidus. It should, however, be bouse in mind that the specific gravity of seecharine urine may be low. Prout mentions a case where it was as low as 1010, and Dr W. Roberts says it may sink to 1015. There appears to be an antagonism between diabetes and gout, the latter ceasing on the supervention of the former in adults.

As the complaint advances, the symptoms increase in severity, the thirst becomes greater, and the appetite is excessive; the patient rapidly boss flesh and strength; the skin is dry and hard, the tengue clean and flabby, or red and aphthous; digestion is detanged, and pain or sinking at the stomach is often present, with more or less flatulence, or even vomiting; the bowels are constiputed and the mind is depressed. In some cases there is sweating at this stage, and even attacks of diarrhous. Inflammatory complications of the pleura and peritoneum may supervine, and later on symptoms of pulmonary phthisis, with diarrhou and hectic Phthisis is the most frequent termination according to Prout. The urine now diminishes in quantity, the legs become ordenatous, and death usually occurs from exhaustion. In some cases death takes phase from cross.

Course.—The disease appears to prevail chiefly in families that are phthisical or epileptic. Dr. W. Roberts alludes to a family of eight children who all became diabetic, though the parents were healthy, and instances are mentioned in which it has appeared through the third and fourth generations. The exciting causes are probably exposure to cold and damp, drinking large quantities of fluid when the body is heated, excessive use of saccharine articles of food, febrile diseases, and meanal emotion. "Glycosaria has been repeatedly observed in cases of paramenia, whooping cough, and phthisis, which lead to deficient exygenation of the blood." Some disturbance in digestion and assimilation appears capable of originating it; the kidneys take an excessive action followed by the usual symptoms.

¹ Op. nt., p. 123.

Lecture on Diseases of the Lines, by C. Marchison, M.D., 1877, p. 558.

Dialectes is sometimes of transmatic origin, following injury to the brain or spinal cord.

The chief tests for sugar in the urine are three:

The Copper Test (Tremmer's test).—Put some of the suspected urine in a test-tube, to which add a drop or two of a solution of sulphate of copper. Liquor poinces to the extent of half the volume of urine is then added, and the mixture boiled. If sugar is present, a residish deposit of the subsocide of copper is thrown down. When there is no sugar, the precipitate consists of black exide of copper.

Felling's solution is a more delicate test than the preceding. Boil a small quantity of the solution in a test-tube, and then add a few drops of urine. If there is much sugar present, a yellowishbrown precipitate of exide of copper will be thrown down. When no change results from boiling an equal quantity of urine and the solution, there is no sugar present. Pellots containing the constituents of the empric test, introduced by Dr. Pavy, are convenient,

and form both a simple and reliable test,

2. More's Test.—An equal quantity of urine is to be boiled with figure potasses in a test-tube, when, if sugar be present, the mixture will assume a dark-brown brandy-color. There is some objection to this test, as the same proceeding slightly darkens healthy urine. "Again, all high-colored urines of high density become darker when loided with higher potasses, although free from sugar, and albuminous urines, even when not high-colored, darken sensibly under the same treatment."

3. The Ferricatories Test.—A little German yeast is to be put into a test-tube, and then filled to the top with the suspected urine. The tube is now to be inverted in a dish or suscer, and put in a train place, or in a temperature of 80°. The urine begins to forment, and carbonic acid gas is seen collecting at the top of the tube, and if there is a large quantity of sugar, all the urine is driven out before it. According to Dr. Roberts, this is a less sensitive method of sugar testing than Moore's plan.

Another plan is to take two glasses of urine; to one, add German yeast, and put both uside in a warm place for twenty four hours; then take the specific gravity of each; the difference will

indicate the number of grains per ounce.

^{*} On Urinary and Eccul Discuss, by W. Roberts, M.D., 1876, p. 183-

^{† (}Ip. cit., p. 18%.

Pathology.—Claude Bernard, in 1845, stated that sugar was secreted by the liver in health, and that if the eighth pair of nerves were invitated at their origin in the fourth ventriels, an abnormal quantity of sugar is produced in the liver. The sugar so formed was supposed to be carried to the heart by the hepstle veins and vens cava, thence it was conducted to the lungs by the pulmonary arteries, and combustion taking place, the sugar was consumed. Further researches have tended to show that it is glycogen, not sugar, that is formed in the liver; but glycogen is a product so readily converted into sugar, that as far as the pathology of diabetes is consorned, the distinction is not impertant.

When the sugar formed in the process of digestion is in excess of the rapacity of the liver to dehydrate into glycogen, then it appears in the urine. Or in cases where oxygenation is defective, and the sugar found in the liver and muscles is consequently not hurst off, then also it appears in the urine. We therefore get glycosuria as the consequence of derangement of the digestive act, or in diseases where the blood is imperfectly oxygenized. Further, "whatever quickens the circulation of the blood through the liver, particularly in the bepatic arteries, favors the conversion of glycogen into sugar, possibly by increasing the amount of albuminoid ferment; and, necoellingly, whatever paralyzes the vaso-motor nerves of the hepatic vessels, either directly or indirectly, dilates these vessels, produces an increased flow of blood through them, and so leads to dilabetes."

Proposite.—This is very unfavorable, the disease being fatal in the greater number of cases, and the younger the child the greater is the fatality. The duration of the disease is variable. It usually lasts from one to three years, "I saw a case, a child of three years, who died in three weeks. Becquered mentions the case of a loy of nine years who died in six days,"! If sugar persists in the urine when the patient is restricted to a purely animal diet, it is of evil orien.

Treatment.—This, in children, is based on the treatment found useful in diabetes in adults; it mainly occasists in regulating the diet, so as to prevent the accumulation of sugar in the block, for on this depends the excessive thirst, the inordinate appetite, and

Dr. W. Boberts on Unimary and Bernd Diseases, 1878, p. 281.

[&]quot; Lectures on Diseases of the Lines, by C. Marchison, M.D., 1877, p. 538.

the constitution. All food, therefore, containing angar, or articles convertible into it, should be avoided, especially bread and justatoes, rice, tapieca, and arrowroot-indeed, all matters rich in starch. Some vegetables, as turnips, cabbage, broccoli, carrots, parenips, peas, asparagus, and scalcale, must be avoided. Endivo. matercross, lettuce, and celery, may be taken. Sweet fruits, as apples, years, oranges, and currants, fresh or preserved, are delutorions. Animal food is chiefly to be rolled on; bacon and ham, fish of every kind, butcher's meat, poultry, game, and broths and soups are permissible. Eggs dressed in any form, ch-se, butter, cream-indeed, every form of fat may be taken. Bean cakes, made after the formula of Dr. Camplin, are very serviceable. They are outirely free from starch, consisting of bran, eggs, butter, and milk. Gluten bread and biscuits, prepared by Van Abbott, Princes Street, London, and similar bread of other well-known firms, is to be recommended. There are also almost rusks and biscuits, introduced by Dr. Pavy, and made by Mr. Blatchley, Oxford Street. These may be taken in change with other suitable forms of diet.

Dr. A. S. Donkin relates the case of a girl ten years of age, who was successfully treated by the skim-niik method. The urine ranged from 1946 to 1945. There was great thirst, excessive appetite, polyaria, and great loss of fiesh. A restricted meat diet, iron, and Dover's powder at night failed to do good, but when the patient was piaced on a skim-milk diet the specific gravity of the urine fell to 1916 within a week, and on the thirteenth day of the treatment it fell to 1912, and not a trace of angar could be detected. In little more than six weeks she had gained five pounds in weight, "This case, and others I have treated, convince me that diabetes is curable in childhood and early life, when the disease is recognized early and the constitution good. On the other hand I have found, contrary to what has been asserted by certain writers, that the disease is quite intractable, especially when considerably advanced, in subjects at or beyond the middle period of life."

Glycerin should take the place of sugar, and in combination with dilute phosphoric acid it allays thirst. Tea and coffee without sugar are suitable.

The patient should drink enough water, and no more than to aliay thirst, and lemon-juice may be added to it.

^{*} Clinical Transactions, vol. iz, p. 39.

Exercise in the open air, short of fatigue, is important.

Drugs have little or no influence over the discuse, the only means that hold out any hope of cure being great care in diet. In the experience of many physicians, opinto, however, is a remedy which, when given in large doses, reduces the quantity of urine. It seems to have the power of diminishing the appetite and thirst, and of inducing sleep and allaying britability. Some physicians have a preference for codein; it is equally effective and less constiputing, Alkalice, arsenic, brounds of potassium, betic acid, and peroxide of hydrogen are all useless. A powder of bicarbonate of soda and rhuburb, or easter oil, by correcting the secretions and reliening constitution, will be advisable from time to time. Iron may possilor retard the progress of the disease for a period where the patient is no emic, and there are no better forms for administration than the ferri re ammonize citras, the fineture of the perchloride, or the solution of dislyzed iron. Cod liver col, too, is useful to support the strength.

The clothing requires to be warm, and flannel should be norm next the skin. A residence at the seaside, or even sea-bathing will be advantageous in some cases. The best foreign watering-pieces

are Carlebad and Vichy.

Finally, all those bygionic measures ought to be carried out which naturally suggest themselves where the kidneys are doing excessive work.

Dialites innipidus is characterized by great thirst and excessive discharge of pure limpid urine of low specific gravity (1966 to 1007), containing neither sugar nor albumen. In a table of seventy cases given by Dr. W. Roberts, seven occurred in infancy, and fifteen from five to ten years. In two or three of the cases the discase existed at birth."

As in distate multitus, the complaint would seem sometimes dependent on gastric and intestinal disturbance, but in a large proportion of cases no cause can be ascertained. Exposure to cold by checking the action of the skin, and throwing more work upon the kidneys, has originated the complaint; drinking large draughts of cold unter, violent muscular exertion, oerebral talencle, felsile discuses, blows and falls, syphilis and harelitary influences appear to be among the most frequent causes. The exact cause has been attributed to some change in the renal capillaries, which allows of

^{*} On Urinary and Benal Discuss, 1876, p. 188.

an increased quantity of watery fluid being separated from the blood, just as happens in a hysterical parexysm. Dr. Handfield Jones considers that the Malpighian capillaries are more affected than those of the tubular plexus.* Some authorities consider the disease neurotic.

Symptoms.-These may be gradual, the disease having lasted from lafancy to maturity in some cases, or it may come on quite widdenly. "In two cases the symptoms commenced immediately after violent muscular effort. One was a boy of twelve, who strained himself in pushing a cart-wheel sank in the mod." The urine is colorless, and containing a very small proportion of solid constituents, having a specific gravity nearly as low as water inelf, 1003 to 1007; it is of acid reaction, but quickly becomes pentral or alkaline, and undergoes decomposition. The skin is penerally harsh and dry, and the thirst intense, arising no doubt from the greater quantity of urine passed than in swecharine diahotes. The general health is often wonderfully preserved, notwithstanding that the disease may have existed from an early period of life. Dr. W. Roberts mentions the fact of a boy of ten years of age under his care, being well nourished and in good health, though he passed fifteen pints of urine daily for several months.* In most instances, however, symptoms psecubling those not with in dialetes mellines are present; there is loss of flesh, thirst, verseious appetite, heat and dryness of the skin, poins in the limbs and loins, and irritability of temper. The disease is of uncertain duration, and generally terminates in phthisis or cerebral discuss.

Pellology.—After death the kidneys have been found degenerated and containing very small absences. The base of the brain has rescaled military tubercles in a few cases. "The pathology of dialetes insightes appears to be somewhat similar to that of dialetes indiates, only that the renal vessels are dilated instead of the bepatic ones."

Transact.—Valerian in large doses is well spoken of by Troussean and Handfield Jones. In a boy, ten years of age, under the care of Dr. W. Roberts, the valerianate of zinc in gradually in-

⁴ Distance Instruction, by Lander Branton, M.D., Reymold's System of Medicine, vol. v. p. 450.

creasing doses, up to twenty grains daily, reduced the urine from fifteen to five pints a day, and greatly diminished the thirst.* Camphor, iron, ergot, and galvanism have been tried with varying success. Mercury and indide of potassium have been found surviceable where the disease is of syphilitic origin. The disease, however, can scarcely be considered amenable to treatment. No remedy has been known to cure it, and it has usually a fatal termination. A normal appetite, and the absence of organic couplication, may be looked upon as favorable signs.

DISEASES OF THE PURITOSEUM.

Active Parameters. Symptoms—Canno-Model approximate—Disposite and proposite—Transmit., Cannotte Printerprint Court and tendenge. Tennertian Printerprints (Tanno Ministerioris). Symptoms—Court—Compared—Radid approximate—Disposite and courtes at Explanationary of the Amounts.

Acure rearrowers is a very mre discuse in children, the noncess membranes being much more prone to inflammation than the serous in the young. When it is present the symptoms resemble those observed in the adult. In the new-born infant, peritoning is more common than in later childhood, and syphilis appears to be a frequent cause of it at that early period. There may be constitutional evidence in the houses voice and copper-colored emption over the body. Rilliet and flarther uset with a dezen cases of acute peritonitis. "M. There found that acute peritonitis existed in about six per cent, of all the infants who died at the Hospice des Enfant trouvis."

Peritonitis, which is rarely a primary disease, may commetee rather suddenly with rigors and shivering; more frequently in comes on gradually in the course of some other disease, with pain in some part of the abdomen, as about the umbilious or hypogastrium, and from thence it spreads over the whole abdominal region. The slightest pressure is intolerable, not even the weight of the heddlothes can be borns; the child lies on his back with his knees

^{*} Up. cit., p. 211.

[#] Discusor of Children, Dr. Churchill, 1858, p. 192.

drawn up, to relax the muscles of the abdomen. The face occurs an anxious and sainful expression, the lips are compressed, and the nostrils netive; the breathing is short and thorners, for us the duplingm descends on full inspiration, the abdominal pain is inercased, but the opigastrium may rapidly rise and fall at the same time. In such cases I have known the respirations to reach 80 per minute. The bowels may be constituted or relaxed, and the urms scanty and high-colored. Occasionally the blodder is paralyzed, and the urine has to be drawn off. The tongue is clean, or it has a whitish fur upon it, which soon becomes dry. There is thirst and loss of appetite. The disease may drag on for some days, during which the akin becomes moist and damp, the pulse Scalde and fluttering, and there is remitting of coffee-colored fluid, besides gaseous distension of the abdonum, torpor of the mental farulties, and death by asthonia is often the result. Sometimes the disease is more limited and circumscribed; it does not extend over the whole abdomen, and yields to the remadies employed.

Casses.—Péritonitis may arise from cold, wet, fatigue, and bad living. A fatal case is recorded by Mr. Jeaffreson, of Newcastloon-Tyne, of a girl fifteen years of age, from perforation of the rectum with a walking-stick, which her uncle was holding between his logs whilst she was jumping on his knee. A rent was discovered in the anterior wall of the rectum, through which the finger could be passed into the peritoneal excity. Peritonish eraned, and death took place within forty-eight bours. It sometimes occurs as a sequel to scariatina.

Dr. Burney Yee has related an instructive case of "infective peritonitis" in a loy twelve years of age, complicating an attack of whooping-cough, and terminating fatally. There was preumonic infiltration of the left lung and fluid in the left pleural age. He quices from Ziemssen's Cyclopedia to the effect, that pus may pass from the pleural cavity through the displaragm into the peritoneum, and there set up fatal peritonitis.) Several cases have come under my notice in which septicecula in women, springing from operations involving the peritoneum, has extended to the pericardium and pleural cavities.

Peritonitis has followed inflammation of the esecusa, from the impaction of a foreign body in the vermiform appendix. The

Brit. Mod. Journ., 1874, vol. 11, p. 400.

[†] Bad., Documber 7th, 1878, p. 827.

disease may terminate in twenty-four hours, or last four or free weeks. It may also follow injuries or operations on the abdomen,

na tappáng.

The more of changes detected after death, are the efficient of lymph over the peritoneal surface and amongst the intestines; the vessels of the peritoneam and abbrevious wall are injected; and there is clear or longer-tinted serious in the peritoneal eavity, or even a thick or thin muco-paralest matter. The splexu and liver may be conted with lymph. In a case related by Dr. West, of a boy, nine years of age, a pint of pass was found in the right plears, the inflammation having extended from the abdomen to the thorax.* This is not an uncommon coincidence.

The dispassis from colic has been already given, that we may repeat that in peritoritis the constitutional symptoms are more severe, the pain is increased on pressure, it is not paroxysmal, and the pulse soon becomes quick and feelde. As the disease assumes a more chronic form, crepitation can often be felt by the hand, when it is haid on the abdomen above the offused lymph.

The prognosis is grave, unless the inflammation is limited in extest and moderate in degree.

Should be applied to the alslowers, and it may be even necessary to repeat them. This requires to be carried out effectually if the ease be seen early, and the child is able to bear depletion well. It offers the best chance of relief. Then warm light poultiess are very conforting, and they should be frequently renewed. Small doses of calonici, combined with epism or Dover's powder, are also surviceable to alky pain and abate inflammation. Opinm is invaluable in peritonitis, and should be given freely. If the bowels are constipated for any length of time, warm-water enemats, and an elastic tube passed up the arms to favor the escape of gas will be advisable. The diet should consist of milk-and-water, this arrowroot, or weak beef ten, according to the state of the standard and the strength of the patient.

When peritonitis succeeds scarlet fever the symptoms are less acute, but, owing to the defective communition of urine by the kidneys, dropsy is very apt to arise.

Chronic peritonitis may be the soquel of an aoute attack, or it

Discount of Interny and California, 8th olit., p. 815.
8 See Chap. XVII, On Constitution and Calic.

may arise from the irritation of tubercles in the peritonena of atrumous subjects. The symptoms are abdominal pain and tenderness, with more or less swelling; sometimes crepitation can be felt from the effusion of lymph between the folds of the intestines. If this does not cause fatal obstruction the case may recover, but where the complaint is due to the irritation of tubercle, the mesenteric glands are upt to become involved, febrile disturbance comes on in the evening, food is vomited, and death takes place from phthis or exhaustion.

The treatment consists in supporting the general strength by nutritions and easily digestible food, such as milk, mw eggs, col-liver ril, or mult extract. A blister to the abdonsen is sometimes of service.

Teles measures in a chroule tabercular disease of the mesenteric glands, and is sometimes associated with tubercular peritoritis, Enlargement of the abdomen is the first symptom which attracts notice, and there may be some amount of fluid in the peritoncal ravity. A child may be quite well and strong till he is seized with who your cough, or one of the exanthemata, and from that period the disease commences. He gradually loses flesh and strength, and if he has been accustomed to run about he now essass to do so; be complains of being tired, and wishes to be nursed by his mother. The complaint sometimes commoners with looseness of the bowels, the motions being thin and reastlike, containing muons or even streaks of blood. Then the alsomen begins to swell, and is tender on pressure, colleky pains are common, and the child will be on his back in bed with his logs drawn up. He often eries out with pain, and the face is pinched and drawn. On examination, the liver may sometimes be felt below the ribs, and the spleen also. As the case goes on, the abdomen becomes irregular in shape, and is some cases crepitus can be detected when the hand is passed lightly over it, from the effusion of semi-organized lymph. As the disease advances, an irregular nodular muse may be felt about the umbiliens, or to one side of it. This is frequently found to consist of omentum, mesentery, and intestines glued together, and among this mass there are enlarged mesenteric glands, sometimes the size of a filbert. As the discuse goes on, some degree of assites is present, and the lumbar regions are dull on percussion. Emaciation sets in, there is constant vemiting and diarrhon, the pulse becomes quick and small, the temperature rises in the evening, and

the child dies exhausted or in convultions. The disease may torminute by brombial phthisis, primonary consumption, or tubercular meningitis.

Discuse of the mesenteric glands may lead to intestinal oscinsion. In the case of a boy, four years of age, who came under my care at the Samuritan Hospital in 1878," there was considerable distension of the abdomen, and symptoms of obstruction a few days before death, which was preceded by coffee grounds vomiting, contribute, and unconsciousness. After death, the intestines and omentum were found glood together in a large mass, and adherent to the peritoneum at the ambilities and brim of the pelvis.

The disquest is generally not difficult; the liver is often healthy, and as the disease advances the fielly becomes irregular over its surface, and more painful than in ascites. There is often a fluctuation in the temperature, and the signs of unbercular mischief in

other organs as the complaint advances.

The tryotocut consists in maintaining the general strength and meeting the chief symptoms as they arise, but it is very meatisfactory. If there is any amount of peritonitis, opium in some shape or other must be given, and linecod poultices be applied to the abdomen to relieve the pain and tenderness. When diarrhou is very active, a little chalk mixture with catechu or krameria (Form, 31, 32) will be necessary, and the diet must consist of rice, milic, and arrowroot. The treatment is much the same as should be employed in chronic diarrhosa. When the borrels are quiet the syrup of the indide of iron and coldiver oil, if the stomach will retain it, should be prescribed. I have found painting the ablemen night and morning with a weak tineture of todine (1 in 1) medul, and then applying a flanuel bundage. I prefer this to rabbing any kind of contment into the abdomen. When the child is well enough to be moved, change of air to the senside will be alvisable.

Enlargement of the abdission is very commonly observed in deficate children who are rickety or of a strumons habit of body, but I have seen it in fairly developed children who are otherwise healthy. The parents observe that the abdomen is disproportionately large to the rest of the body, and that it becomes very much as after food. In many cases the increased size is chiefly due to flatte in the intestines, to constipation, and improper feeding. The abdomi-

^{*} Lancet, Aug. 18th, 1878, yr. 185.

ASCITES. 299

pal walls yield and become overstretched; the abdomen is soft, pressure gives no pain, and no tumor can be felt. This condition is sometimes seen with congestion of the liver, and with that condition known as "pot belly." I have noticed it not rarely in delicate children after an acute illness, as whooping-cough or member. In children brought up by hand, with delayed dentition, it is not uncommon. It arises chiefly from the accumulation of gas in the intestines; a clear tympanitic note is heard all over the abdomen, especially in the left hypochondrism, and in both flanks. The spigastrium is prominent, either from undue distension of the stomach, or of the transverse colon behind it. "The little child's abdomen is large because its abdominal and intestinal muscles are weak, its pelvis is shallow and small, its disphragm flat, and its liver and spicen large, and because much flatus is formed in its small intestines, especially during the digestive process."

Enlargement of the abdomen, when seen in connection with tubercular peritonicis, causes pain on pressure; the abdomen is irregular in outline, partly from the calarged viscora beneath or from semi-organized lymph; the bowels are often very loose, and the belly painful; the face is pinched, and the child rapidly loses

flesh.

The liver may remain very large without any impairment of the general health, a condition we sometimes see in connection with the strumous diathesis and general cuchexia.

CHAPTER XXVI.

ASSITISA.

Course—Nature—Symptoms—Diagnosis—Treament—Free—Selter aprivate— Gyallo—Percontant

Distant of the liver, by obstructing the portal circulation, is the most common cause of ascites in children, but it may arise also from great enlargement of the spleen, from chronic peritonitis, and from takes mesenterica. The enlarged glands in the latter disease cause friction and irritation of the peritonoum, and so lead

On Extra-policic Tunness of the Abdoman, by Sir W. Jenner, Earn., M.D., Brit. Med. Journ., Jun. 3d, 1869, p. 2.

to serous efficient into the cavity. It has been supposed to arise from the personre of enlarged lymphatic glands on the pertail van ucar the liver.* It appears to me that eachexia and amenia are not uncommon causes of this form of dropsy. In the absence of any history of acute illness, and if organic disease is not present, it seems a reasonable inference that a loss of tone in the peritoneous or lymphatics may favor the secretion of serum into the peritoneal cavity. I have published a case in illustration of this view.

Symptoms.-The abdomen is more or less prominent in propertion to the amount of fluid present. If the distension is great the displangm is pushed upwards, and there may be some duiness or percussion and defective expansion in the lower lobes of the lungs. Over the seat of effusion the percussion-note is stull, chiefly burd in the flanks, and more in one flank than in the other when the putient turns on his side. Along the anterior surface of the ablomen the percussion-note is clear, and this varies according to the amount of air schiol the intestines contain; the higher they foat the more sympanities is the note. The constitutional symptoms are a gradual decline in the general health; the skin is dry; the borrels are usually constipated; the urine is scanty, neid, and highcolored, from the presence of urates, which may be whitish instead of pink; there is often thirst and a voracious appetite. As the abdominal distension jurrenses, the superficial veins become anlarged and tortness; the child is thin and wasted, the features are pinohed, and the nights restless and wakeful. As the discusadvances the emaciation increases, a bertic flush appears on the cheeks at night, the pulse becomes rapid and feeble, respiration is accelerated, and death takes place from exhaustion.

The disgress mainly rests on the primary and uniform swelling in the abdomen, without any orderns of the logs, and the absence of swelling in the upper parts of the body, the presence of disease in the liver, and the high-colored, scanty, and non-allemators urine. As ovarian cysts have been met with in children, this face should be borne in mind in all cases of doubtful diagnosis. Hydrid cysts of the liver, hydrocephrosis, onlarged spless, and measured glands must also be taken into consideration, and the conditions

^{*} Brit. Mod. Joseph, Nov. 20th, 1875.

ARCITIS. 301

belonging to each carefully investigated. The chief points of diagnosis in the case of ovarian tumors, as distinguished from serites, are to be found in Mr. Spenser Wells's work.

Treatment.—This to a great extent depends upon the cause. If there is disease of the heart, lungs, or kidneys, these affections must receive appropriate treatment; but usually, however, the mischief is scated in the liver, which we must endeavor to overcome. Whatever may be the cause which has induced the disease, the bowels should be kept freely open, and for this purpose the compound julip powder, given early every morning, is a good remedy to drain off the fluid. When the arine is scanty and high colored, digitalis and citrate of potash will relieve the conjection of the kidneys and act as a brisk directio. Then the symp of the indide of iron is a good tonic, or the tincture of the perchloride of iron may be given. Ascites has ever and over again yielded to tonics, and they ought to have a steady and fair trial where the effusion appears to be independent of any organic lesion.

If these remedies fail, as they frequently will do, copaids is an excellent remedy, according to some authorities, acting as a dinretic and carrying of much fluid by the lowels. In the case just alluded to, I believe its action was that of a general tonic and not that of a discretic. It does not disagree with digestion or appetite. Other cases of ascites are recorded which have yielded to the use of copaids. Dr. Liveing's two cases of improvement seemed due to its action as a discretic, but it should be held in mind that the urine was albuminous in both, and remained so when the patients left the hospital, although the dropsy had entirely disappeared. There was chronic (Bright's) disease in one, and a soft systolic bruit at the cardine apex in the other, so that the restef at best was only temporary;

When all drugs have proved unavailing, and the increasing pressure causes pain and discomfort, paracentesis must be had recourse to, and the operation should be performed before the abdomen is too much discended. The tonic treatment and the ropails may be again employed after the appling, and a permabent cure may follow the operation in some cases when it has

^{*} Discuses of the Oraries, 1872, p. 125.

Case of Austin treated assessfully with Torics by J. S. Bristows, M.D., Clin. Trans., 1803, p. 12.

been twice performed. Such cases seem generally due to liver disorder, or to debility and angenda.

CHAPTER XXVII.

INTESTERATE WORMS.

Finding of --Decided Cremitedating on Assault Vermitedatin --Assaults (Transform) -- Assault Louisionium (Bother word): Spapers -- Class--- Transform) -- Transform -- Transform (Louis Transform) -- Transform Transform : Transform -- Transf

The presence of worms in the intestinal canal is one of the commonest troubles of childhood. Worms produce in some cases an amount of constitutional disturbance and local irritation which the best observers may be paraloned if they attribute to specific disease.

It is with the two nematodes, Oxyevis and Jameis, that we have generally to deal in childhood. The Oxyevis reminderin, or threndu orm, has its headquarters in the execum, but frequently descends to the lower part of the large intestine or rectum. We may infest children, whether living in country districts or in the contined dwellings of houses and cities; but their presence is not necessarily incompatible with previously good health. They are not uncommon in strumous subjects, or in children labering under chronic disease, in whom the digestive and assimilative functions are at fault—where there is subscute inflammation of the intestinal glands (muco-enteritis). They are often spoken of as "ascutiles," since Linnous placed their species under the genus Asonic But the term is confusing, as they have long been classified under a separate genus, Oxyeria, and must not be confounded with the long warm Asonic (sentencides.

In a mass of Grysei, or threadworms, the majority are females, and appear like little moving pieces of thread, about a quarter of an inch long, with a pointed tail. The males are shorter, and keep the anal end of their body more or less coiled up. The eggs are commonly introduced by the habit which children have of liting their nails. They are hatched in the stomach, the larve undergoing their subsequent growth and metamorphosis within the alimentary cared.

Samptons. - The appearance of the parasite in the motions is of course the only pathognomonic sign; as it almost exclusively inhabits the large intestine, it is very rarely vomited like the true. Asseria," though the constitutional symptoms are the same in both affections. But the presence of threadworms in the bowels excites symptoms of rothex irritation, by which they may be suspected before they are seen. Itching of the nose and anus is the most frequent feature of this kind. At night the irritation becomes an great that sleep may be prevented, and in any case the child is certain to indulge in the dirty habit of continually touching the anns. The finger nails often excoriate the skin around that orifice, leaving marks once erroneously believed to be caused by the bitting of the worms. The irritation causes a free discharge of mucus from the lining membrane of the intestine, and the child constantly voids this at stool by straining, and thereby often producing prelapsus ani. The worms appear in the motions in great numbers, and escape of their own accord from the anus; they even enter the vagina in female children, and set up fencorrhosa. Symptons of vesical irritation also develop themselves, sometimes simulating calculus, more usually seen in the form of a frequent desireto pass water. Priapism is also not unfrequently observed in male children troubled with threadworms, and Lallemand was of opinion that in this manner the parasites produced the habit of mastarbation, with its consequent evils. All general disorders, especially those of the nervous system, are aggravated by the presence of threadworne; this particularly applies to the spastic contractions of muscles which produce some forms of talipes.

Treatment.—As the threadworms are mostly conduct to the lower part of the large intestine they are within the across of ensures. An injection of infusion of quassia, mixed with tablesalt or sulphate of iron, is perhaps the most effectual method of treatment; but as it seldom or ever effects a cure at once it must

^{*} Bit Graders, in his recent work, Des Vers ches les Enfants, remarks that "they can never reach the stomach or the small investing, and consequently can sense be thrown up in veneting, as Brokn and P. Franck have asserted." But Dv. Parapa describes a case where a child aged ten was treathed by Ouyers appearing in her ascend in the creating, Lend. Med. Record, 1878, p. 424.

be frequently repeated." Lime-water is another good application. Since the bowels generally set irregularly when threadworms have remained long in the large intestine, the treatment should be conmescel in all cases by the administration of an alterative aperent. such as gray powder and rhuburb, or rhuburb and soin. When children are strong enough, one grain of calomel and three of scammony is a good operiors to start with. The mucous discharge produced by the irritation of the parasites appears to afford lody. ment for them, and so must itself be cleared away to lasure their complete expulsion. They rapidly reappear. Two or three grains of santonin at night, followed by a dose of castor oil in the morning, will effect the discharge of these threadworms. Afterwards steel wine, or the tineture of perchlorade of iron, will be useful. - Iron, in these circumstaness, acts, I believe, not merely as a toric, but also by its admixture with the secretions, it renders the latestinal mucous membrane unsuitable to serve as a nidus for the reproduction of the worses,"

Dr. R. Liveing informs me that as a local application, about an equal quantity of mercurial cintment and lard, smeared on the and aperture at night, will prove effectual in relieving the itching and preventing the escape of the worms and ova. The child thus gives up the habit of scratching with the fingers, by which the ova are introduced under the sails and then conveyed to the mouth.

Children should not be permitted to drink unfiltered water, for to eat saind, radiabes, or cross, unless theroughly washed, as the ova of the Gryan's are possibly transmitted in this way. It a significant that of country children, the peasant class are the most subject to intestinal worms. Of course they have more opportauities of drinking out of wells or brooks, and of eating raw fool, than have young people in town. So long as infants are fed with breast-milk they are not troubled with worms.

2 West, so Discuses of Indiany and Childhood, 1858, p. 627.			

The Ascer's fundriciales, or round-worm, by no means rare, is however less frequent than the threadworm. It is best to distinguish the two species by their English names, for, as I have above remarked, the generic name Ascer's is still retained by many in speaking of the Organia, though the two worms are very hifferent in appearance. The round-worm is a very large parasite, always several inches in length when full grown, and sometimes a fost long. It bears a strong superficial resemblance to the common earth-worm (Lambriesa terrestris), which is not a nematode at all, nor even does it belong to the class Scalerids. The earth-worm is included in the sub-kingdom Annulosa, and, like the leach, it differs from the Crustacca in lacking true feet. Independently of the different internal structure this norm is much structure than the Asceria, and bears eight rows of minute bristles, which give its integuments a rough feeling.

The male Asserts is curved as in Oxyaris. Davoine has shown that the female produces over 50,000 eggs! That observer, confirming previous researches, has proved that the eggs do not hatch in the intestine of the child in whom the parent worm dwells. The over are expelled in the freeze, and find their way into savage-mater, etc. They are absolutely indestructible by any natural force, though beiling, or many other artificial processes, will destroy them. They are introduced into the bowels by unfiltered drinking-water, etc., and, being dissolved by the action of the digostive juices, the embryos which they contain are set free."

Not only does the Asseris differ from the Oxyeris generically, but it differs also in habitation. It dwells in the small intestine, often in numbers, but never in such masses as are seen in had cases of accumulations of threadworms in the rectum. It is not unfrequently venited. A country-woman in one of the wards of the Samaritan Hospital, in the autumn of 1878, brought up a lumbricus during an attack of sickness after ovariotemy. Mr. Alban Drean informs me that a man in St. Bartholomew's Hospital, in

The works of Coldeid and Emchanasister should be consulted by those desiring minute details with regard to enteres.

1870, vonited several when dying of dysentery contracted a few months before in Buenes Ayres. Still oftener do children throw up round-worms, and in violent retching the parasites may be expelled through the mares as well as by the mouth; or they may remain in the most ravities a short time, and suddenly appearing out of the nestrils cause great alarm to the petient and his parents. The America sometimes escapes out of the cavities of absorbed formed after perityphilitis when such collections of pas are opened spontaneously or surgically. They may also enter the peritoneal cavity through typhoid or gastric perforating alcers. But Davaine has shown that it is quite impossible for the worm to free its own way through the costs of the intestine, as it is not provided with entring or boring appendages.

Symptons.—This worm gives more trouble than the Oryaria, and often produces much reflex irritation. The lowels not in an irregular manner, dull pain is felt around the umbilious or in the opigustrium, and there is itching at the nose and auge. Any maledy from which the patient is already suffering will be aggravated. But since, as in the case of the threadworm, the appearance of the worm itself is the only reliable symptom, it is nost unjustifiable to subject it child to a long course of worm medicines on suspicion alone. If the worm really exist in the intestine, it will soon be discharged in the motions after a few days of treatment. It must be remembered that in cases of round-worm some morbid condition of the intestinal nancous membrane very often pro-exists.

Visitorial.—Prophylaxis is more important and more effications in the management of disorders caused by this parasite than in cases of invasion of the Organic, for the round-worm always appears to be introduced, as an egg, in water, whether taken pure or with raw food washed for the takin. As for cure, the physician, knowing that these parasites often do little harm, must not forget that Davaine has recorded several fatal cases where a round-worm has found its way through the glottis during a fit of nomiting. Moreover, the rulex results of the presence of the parasites induce dirty habits, such as picking of the ness or scratching the annu.

By far the best remedy for the round worm is sentenin. From one to six grains abound be given to a child, according to age; if may be administered in a powder mixed with segar,* or as the songound scannoony powder.† Dr. Enstace Smith speaks highly of antonin in the form of confection... It is advisable to follow up its administration by a dose of easter oil, and then to give tonics, particularly steel wine, of the mineral acids with some bitter infusion. I am in the habit of giving the matonia every other night for about four nights, and during the day a tonic of irre, arsenic, or quinine. I asserting combine these three remodias together, but I am generally content with the two first (Form 93). The persistence of the parasite after long treatment will next likely be due to the neglect of prophylactic measures, such as a careful examination into the mater supply and the sanitary measures.

Another nematede, Trichespheles disper, infests the excum and salou. It measures over an inch in longth, and the anterior part of its hedy is filiform, the posterior being much steaser. It is remarkable for preducing, as a rule, no symptoms of irritation, and it is only recognized in lifetime by the appearance of its ora in great quantity in the frees. It may be expelled by done of

suntonin, or active aperients.)

Theyworm.—The tends are Seclecida, arranged in a distinct order very different from the nematodes. Their anatomy is very

complicated, and their method of propagation has already been described in the chapter on "Hydatid Discuses."

"The tenta† is rure in chibihood; in 206 of Wawruch's cases, 22 were children under fifteen years of age, the youngest was 3½. Logendre (Archives Giocrafe de Mélécies, vol. iv., p. 642) has collected from different authorities 26 cases of tapeworm in children under twelve. (In children from foorteen to fifteen months of age, 2 cases; two years old, 1 case; three years old, 2 cases; four years old, 2 cases; five years old, 3 cases; six years old, 4 cases; seven years old, 4 cases; sight and nine years old, 1 case; ten years old, 2 cases; eleven years old, 4 cases; twelve years old, 1 case.) Hufeland, quoted by M. Davaine, has seen an infant six months old, and at the breast, subject to tapeworm; con different occasions he passed up to twenty meters (over sixty-five feet) of tamia, sons sociolest pricationant over as same."

The treatment will be similar in childhood to that adopted for adults. The remarkable words which we have left in their original language at the close of the above quotation fortunately apply, at least to a great extent, to most cases. The extract of unleform is as efficacious in the young as in the old. It is a good plan to see that the bounds are effectually emptied before beginning the specific treatment, and to attain this end a mild aperient should be given occasionally, and the diet, for a few days, ought to consist only of milk and beef tea. When the attempt is unde to dislotige the parasite a dose of castor oil should be given at night, and the oil of male-fern early on the following noming.\(\frac{1}{2}\) Foreign writers prefer pomegranate and kouses for children. Goulert gives 15 grams (equivalent to 231 grains) of pemegraate root back, in deception, to children under five, and 2140 grams for a child from six to twelve, in 750 grams of water.

^{*} The Massau of the College of Surgeons contains resources specieses of the bod tigeworm; T. neckonsellate; One of these is from a tinte girl (Estate serie, Sp. 110). to be taken in three doses at inservals of half an bour, followed by easter oil if the parasite be not passed within six hours.

The exotic and rarer parasites hardly come within the scope of this work. But, in conclusion, a few general remarks may be made on the symptoms which worms are capable of producing, and how difficult it is sometimes to form a diagnosis.

Symptoms of an obscure and deceptive character, which cannot be classified under any definite disorder, and which vary from day, to day, are frequently cleared up by the discovery of worms. Lurking mischief in the long or brain has been apprehended in some cases, or the approach of fever has seemed imminent in others. Fits of passion, violent screaming, restless sleep, and even fits of opilepsy or chorea, have been ascertained to depend upon these purseites in the intestines, and the symptoms have been found to pass away on their expulsion. A chibi so affected loses its animation, and is languid and out of sorts; it suffers from healache, and its temperature is high in the evening. This has been known to reach 105°, or more. The child becomes weak and thin, and coases to thrive; the appetite is capricious, and it sometimes refuses almost any kind of food that is offered, while at others it is quite ravenous; the eyes are dark and hollow, the tongue is furred, and there is sometimes a dry backing cough, which makes parents anxions, although they are assured that no lesion in the lungs can be discovered. Such cases are often ascribed to commencing tubercular mischief in the lungs or benin, and the lest observers have been misted in their diagnosis. The cough being the result of intestinal irritation the child recovers its usual health as soon as the worms are removed.

These symptoms are very treacherous, and they continue so obstinate in some cases that only time can clear up their true massing. They may simulate brain disease by the occurrence of a convulsion followed by squinting. Vegel mentions the case of a child who was attacked by convulsions, and a few days after with all the symptoms of acute hydrocephalus, followed by death in a few hours. On a post-mortem examination, the brain and all the internal organs were found in a perfectly healthy state, "but in the intestinal canal there were more than a hundred round worms, relied up in small and large balls, at some points completely choking up the callibre of the canal; the mucous membrane itself in the same regions had become reddened."

^{*} Diseases of Children, 1971, p. 207.

CHAPTER XXVIII.

DESERTED OF THE NAMES CANTELLS.

CONTRA-NAME CATHERY (COMMON CORP. ON COMMON THE PRESENT AND ASSESSMENT OF THE PROPERTY OF THE

The entire nancous membrane in infancy and childhood is prose to morbid action, commencing at the mouth or nostrils, and frequently exciting cataryh, not only in the larynx and sir-passages, but in the intestinal tract also.

The mucous membrane of the nose is fiable to hyperemia, inflammation, and tumefaction.

Coryga, or cold in the head, is a common aliment, and is frequently observed in delicate and strumous children. It is most common in winter, but it may occur at all seasons of the year. It may be associated with bronchitis, laryugeal catarri, measles, whooping-cough, etc.

Conses. These are exposure to cold when the surface becomes chilled. There is, according to Rosenthal, a heat-producing area and a heat-radiating area, and when a loss of balance takes place between the two, a chill to the surface brings about this frequest nilment. If heat-loss and heat-production are equivalent, no harm results from exposure. Whenever a person is exposed to rold, the cutaneous vessels undergo contraction, so that the blood accuralates in the internal organs, and more animal heat is evolved than is usual. Hence a child more easily catches cold if it is not suffciently protected by proper clothing, or the temporature of the rooms in which it lives and sleeps is too low. When, on the other hand, the atmosphere of the room is too hot, or active exertion is undertaken in it, so as to induce from perspiration, the result of the skin dilate, and animal heat is freely given off. The vasomotor nerves of the vessels of the air-tubes become partially paralyxed, and hence a catarrhal state is easily set up. If now, at often happens, the child exposes itself to a draught of cold sir, or goes into an apartment that is many degrees too low, then the vessels which are dilated less their power to contract, and the

blood, instead of passing freely through them as before, stagnates in them, or accommulates in the deeper tissues or organs of the body. All the morloid elements, instead of finding an outlet through the skin, accommulate in the blood, to the detriment of the patient's general nutrition. If the atmospheric air inhaled at the same time be not pure, another evil is added; the lungs, like the skin, do not part with a sufficient quantity of carbonic neid, and the condition of cold may lead to some more serious state. Every case is not equally severe. When the blood is only slightly contaminated with refuse products, the outsucous vessels, after moderate dilatation, soon resume their normal calibre, and a cold is either avoided altogether, or it is very transient in duration.

Living in rooms above a temperature of 65° predisposes to cold by weakening the system. "There are few causes which promote susceptibility to cold so much as sleeping in close rooms; the blood being thus charged with carbonic acid and other fool gases is prome to stagnate, and thus congestion, the first step to catarrhal inclammation, occurs."

Local irritation arising from fog and mist, the entrance of dust into the nostrile, air laden with pollen from kay, and repeated Howing of the nose, are all exchants of much catarrie.

The most intense useal catarrh is sometimes induced by taking a few grains of iodids of potassium. I myself suffered from sleeplessess and severe pain across the frontal sinuses, with great irritation of the lining membrane of the nose, and a peculiar sensation of falmoss and tightness news the forehead, in consequence of taking this drug. The discomfort was so peculiar and severe, that I never before experienced anything at all like it from the most severe catarrh.

Pottology.—The capillaries are swellen and engarged with blood, producing hypersonia and congestion of the naucous membrane. This furnishes an axid, saline, and watery secretion, which inflames and even executates the lips. In severe cases, the submucous tissues are infiltrated, and the pharyogeal glands are enlarged, or even ulcreated. As the swelling of the naucous membrane diminishes, the discharge becomes thicker in consistence, and even purulent in character.

As to the possible contagion of catarrh, it cannot be denied that the frequency with which colds run through a household seems

^{*} Come and Coughe, by E. Symes Thompson, M.D., 1877, p. 26.

to prove that those who suffer may by contact impart it to the healthy. Using the same pockethandkerchief may become another medium of conveyance. The contagious principle given off by succeing or coughing may excite irritation in a healthy mucous membrane, and produce entarth.

Symptoms.—The cartiest symptoms are those of dryness and titiliation, with the sensation of obstruction in the nostrils, which induces a disposition to blow the nose frequently. This is accompanied with specing and pain across the frontal sinuses, or even headache; the voice is thick and much the conjunctive are injected or inflamed, and tears run down the checks; if the disconsiort is so great that there is much blowing of the nose, etnoiderable epistaxis may result; the larynx may be involved, inducing screeness and hearseness, whilst the catarrh may extend up the Eistachian tube, producing deafness and singing in the ears. There is more or less febrile disturbance, less of appetite, and thirst.

A large number of cases of incurable deafness, chronic conjunt. tivitis, and inchrymal disease have been traced to frequent attacks of coryga."

Treatment.-When an acute entarrh is developed with febrile disturbance and running of the nose, confinement to bed in a warm room, fluid food, and diluents will be necessary to encourage phoresis, and so relieve the internal organs from mischief. A warm lineed poultice covering the entire chest is often comforting and beneficial. Trecucuanha, small doses of tartarated antimony with liquor ammonise acctatis (Form, 7) will be mitable; while a saline apprient (Form. 8) will cool the system, and bring down the fever. A pleasant cooling drink may be made by abling one teaspoonful of acid tartrate of potash (cream of tartar) to a pint of barley-water, sweetened and flavored with lemon-suice. It acts as a refrigerant, diuretic, and aperient. A correspondent speaks highly of full doses of the tincture of beliadorna night and morning in severe coryza. Two doses generally complete the cure. As children bear this drug so well it may be given in suitable cases ? Fruit lozenges, and lozenges of Iceland moss and chlorate of petrah are demulcent, and encourage secretion. Morphia and other sedatires require to be given with great care to children, for by arrest-

^{*} Brit, Mod. Jour., vol. 1, 1880, p. 419.

¹ Da., vol. i, 1877, p. 220.

ing secretion they may increase the congestion of the muccus membrane, and derange the health.

Ourses.—The nucous membrane of the nose is also liable to an eczematous or ulcorating surface, from which a thick, irritating discharge escapes. The nucous membrane is thickened and congested, as in ordinary catarrh. This is followed by the drying up of the secretion into thick crusts, which almost close the nasal cavities, and become a source of great annoyance to the child. When these crusts are removed the surface is found alcerated beneath.

"In many instances we find the posterior wall of the pharynx covered with similar crusts." The discharge is muco-purulent and blowly, escaping from one or both neutrils, highly offensive in eder, tedious in duration, and difficult of cure. When the patient lies down the discharge may trickle into the larynx, and set up congestion and irritation there.

The leading feature of ozena is intense feter of the breath. The discharge may be too effensive for the patient to go into society, and yet the musal bones remain marfected. When the discharge is of this character we may suspect that discussed bone is at the root of the evil. There is semetimes burning and throbbing pain in the nostrils, and the integumental covering of the nose is red and swellen when the discharge does not freely escape.

Cours.—These discharges are not with in delicate children, and not unfrequently follow tedions cutarrh or the cruptive fovers, as mustles and searlet fover. Ozena may be associated with syphilis and scrofula. A blow on the nose may act as an exciting canso.

Mr. Warrington Haward, in an excellent paper on ozena, from which I have guthered much information for this article, classifies the disease under three principal heads: 1, Scrofulous ozena. 2, Syphilitic ozena. 5. Traumatic ozena. He also mentions an "idiopathic ozena" not referable to either of the above causes?

Scriftless Oretas.—A large number of cases of exem appear
to arise from screfula in children. The skin and mucous membranes are especially fixeds to be affected in this diathesis, and
hence we see troublesome eczema, strumous ophthalmia, otorrhous,
branchial affections, and chronic distribus. Children with this

Niemeyer's Touthook of Practical Muticine, 1875, vol. 4, p. 230.

[†] St. George's Hospital Reports, 1874-1876, p. 130.

constitutional taint suffer from colarged corvical glands, which sometimes observed and are slow to beal. The ansal mucous membrane is thickened and swollen, and pustules and small round alores are seen on the lining membrane. This form of scrotula is often accompanied by troublesome extens (Haward). The terrible feter of extens is owing to the discharge being either pent up in a cavity from which it connect escape, and therefore it decomposes, or to the presence of a piece of dead bone. In the latter case no antiseptic injection will be of any service till the necrosed bone has been removed.

- Syphilite Orano.—Syphilis is the next most common since
 of ozera, of which there are symptoms not to be mistaken. The
 ulcers are superficial or deep, excavated and sloughing; they are
 larger, fewer in number, and more irregular in outline than in the
 preceding variety. When the bene becomes affected the discharge
 is most offensive.
- E. Transmit exerce is the result of injury to the nose, or of the presence of some foreign body. This sets up periestitis, followed by necrosis of the bone, and the cure depends upon its removal. In children, pans, beam, bits of wood or pencil are senetimes thrust up the nose, giving rise to inflammation and alcenation of the mucous membrans. If the offending body is removed before the bone is discussed, the discharge, which depends on a local cause, usually soon ceases.
- "Alloyattic corner," according to Mr. Harrard, seems to frequently follow scarintina and measles. In my own experience a very severe case of ozena followed measles in a child who had no constitutional taint. A thin, semi-poruleut, and sometimes glesty discharge continued for many weeks, but ultimately censed. The meast movests membrane was red and swellen, and easily bled on examination or blowing the nose.

When purulent matter is pent up in the sinuses there is severe frontal headache and sleeplessness at night. Cases are mentioned where the discharge has found its way into the cranism, or the sinus has become so distended that it has encreached on the orbit and displaced the eyeball.

Treatment.—With the aid of the laryngoscope, the must cavities, proviously washed out by means of the must douche, can be well examined. Mr. Haward also recommends that the nestric be dilated by Franckel's speculum, which he says is the best. In the treatment of surgislous arosso, the general health must be attended to. Cod-liver oil, steel wine, the ammonio-citrate of iron, or reduced iron, will be accessary. The musal cavities may be washed out frequently with a adultion of commercisals (but an ounce to a pint of slightly warm water), or tincture of myrrh 5ij, chlorate of potash 5ij to a pint of water, or 3ij of Condy's finid to a pint of water. Sea sir is of the greatest utility.

In the treatment of systellite eros as mercury must be employed, and the best mode of using it, according to Mr. Haward, is the calcular reportbath, recommended by Mr. Henry Leo. Hyd. c. crots for children is valuable, whilst iron, bark, existiver oil, and indide of potassium are to be given at the same time. As a local application, when the bone is not affected, Mr. Haward recommends an ointment of fifteen or twenty grains of red oxide of mercury, and clive oil and hard, of each half an ounce. After syringing with the most douche, this should be applied with a brush. He also speaks well of the mamoulo-chioride of mercury sintment, with olive oil.

In the traveness of the traveles form, antiseptic washings will be needed, and the negrosed bone must be removed if present.

For the management of the idiopathic forms, the general health will require attention, and the application from time to time of a lotion of chlorate of potash and myrrh. Glycerin of tannic acid and dilute mercurial continent are also useful in some cases.

Carbelle acid has been found very serviceable in ozena, and in other discharges from the nose and throat. All muons should be first cleared from the affected parts by a weak alkaline aduttion, and then carbelle acid (1 in 40) should be injected along the floor of the nestrils, or into the pharynx, as the case may be:

A diluted tineture of lodine (1 in 30) may be sometimes injected into the nostrils with advantage.

In chronic ozena, where the nurous membrane is in a relaxed and weak condition, twenty to thirty grains of alum, added to sight onness of water, form an excellent application. It should be injected up the nostrils with a bottle syringe, or one end of an elastle tube may be inserted in a basin containing the solution, at a proper height, and the other placed in the nostril. If the head is bent forward and the mouth kept open, the fluid will permeate the manificarity and run out of the other nostril. Carbolic acid is preferable where there is much fetor.

Mr. Pugin Thornton recommends a cold lotion? to be injected daily up the nostrile by means of a hand-ball spray apparatus, He says it has succeeded in very obstinate cases, after the inhalation of camphor, benzoin, and curbolic sold had failed. Eight or ten applications have cured the most obstinate cases.

Glycerin of tannin is another application, particularly useful in syphilitic owens. Iodide of potassium may be cautiously gives, but small doses of mercury with bark or iron in such a case would be preferable, as this salt so often induces nasal irritation.

Nitrate of silver (gr. v ad 5j) is serviceable where the mucous membrane is swellen, and the complaint seems within reach.

In those cases that resist all medical treatment, a surgical operation may become necessary.

Epistexis is the most common form of spontaneous hemorrhage, arising in all likelihood from the slender resistance which the walls of the vessels afford to the force of the blood-current. The rupture, too, in many instances, probably depends upon a morbid state of the capillary walls or the homorrhagic diathesis.

Among the causes which predispose to this affection are catarria and whooping-cough, tuberculosis, disease of the spicen, and the examthemata. A hiow or fall on the nose may excite bleefing at once. One of the worst cases I ever now was that of a girl suffering from typhoid fever, where the blood had become thin and deteriorated. Plugging of the posterior narcs was required to arrest the profuse bleefing; the patient bled from the bowels and urinary tract at the same time, and the body was covered with hiemperlangic spots (petechine).

Epistaxis is rarely seen in very young children or in those who are strong and well developed. It is most common in the delicate, who have weak muscles and thin bones. The blood may flow from one or both nostrile, either in drops or a full stream. If the homorrhage should happen during sleep, the blood flows back into the pharyax, and excites cough if it gets into the laryax, or

The Treatment of Oness, Brit. Med. Journ., 1889, vol. 4, p. 475.

romiting if it goes into the stomach. If, as often happens, coagulation takes place quickly, the homorrhage is speedily checked; but if the blood be thin, the tendency to congulation is so slight that the patient may bleed till the lips and face are pullid, the conjunctive blanched, and the skin is of waxy whiteness. After continued and great loss of blood, the heart becomes weak and irritable, there is faintness and prostration, the surface is damp and aweating, there is restlessness, headache, and even delirium.

Treatment.-Absolute rest in bad, in a semi-creet posture, should he observed in all cases of most hemorrhage where the loss is considemble, and the effects of the drain are telling upon the system. It is most important to avoid blowing of the nose, which, however, in children is by no means easy to present. Holding the nostrils tightly between the flugers, and applying cold to the bridge of the nose will stop the homorrhage in most cases. If this fail, the injection of load water up the nestrils with an ordimay bettle syringe may prove effectual. The introduction of powdered alum, or oxigalls has sometimes succeeded. Internally, gallic acid, sulphuric acid, tincture of the perchloride of iron, and ergot will be sultable remedies. Sir T. Watson mentions the simple expedient of the patient mising one or both arms above his bend, and of maintaining them in this position for some time." In cases which resist all ordinary treatment, we must have recounce to the appleasant operation of plugging the posterior sares.

Larguaged and Tracked Training in Young Children.—No somer is the respiratory apparatus called into play than it becomes liable to disease, and it remains so from infancy to old age, especially in this variable climate. We have recorded, on the authority of Orfila, Cruveilhier, and others, that traces of inflammation and its products are even sometimes met with in the broughlal tubes and structure of the lung during fetal life. "The great transition," says Dr. Churchill, "from the atmosphere of uterine life to the severe and changeable atmosphere of extrautorine existence, renders the infant pseuliarly ansceptible." Exposure, as in dressing, to draughts of cold air, readily excites the muccus membrane of the air passages, which becomes vascular, tender, and irritable. At certain seasons of the year, when the thermometer is lower than usual, affections of the breathing organs are very common among young children.

^{*} Principles and Practice of Medicine, 4th edit, vol. i, p. 79%.

Bronchitis, croup, pneumonia, arising from cold or as a sequence of scarlation and messles, come constantly before us; but there is a condition, not expressed by either of these terms, which is ape to be overlooked, from the absence of marked physical and general signs, and from the insidious manner in which it commences and steaks on. This condition is at first one of purely local irritation, occupying the laryex and trackes, neither extending to the pharyex and tousils use into the bronchial tuies.

A very common mode of its commencement is the following: The nurse observes that the child (probably from one to two years old) is quite well, with the exception of a slight cold, but there is no cough or other disturbance of the system; all the functions are regular, and the shild sleeps well; it perhaps looks pallid, and the nostrils and upper lip are red, caused by frequent wiping of the nese, as in obter children and adults when suffering from catarria This state of things goes on for several days, and if the weather should become mild, the child goes out of doors as in health, and the cold-for it seems no more-pames away. Should dream-stances, however, prove unfavorable, these symptoms are somseconded by a short, shrill, barking cough, mattended by the prolonged inspiratory effort of eroup and laryngismus; the pulse is quiet, and there is no fever. If the modical attendant is consulted at this stage he observes nothing of importance, the muscles of the larynx and nock are tranquil, and the child when askep leans his head forward on his chost. The nurse will tell you that the cough is the only symptom worth notice; that it wakes the child, and makes him precish and fretful-no doubt from the extreme tenderness and irritability of the membrane involved. The chest is clear on percussion, and there are no moist sounds from base to apex. The affection is often ascribed to testling, and on looking into the mostly the game may be inflamed from the pressure of new teeth. Another day slapses, and perhaps in the night the child starts up in his sleep, finded and excited, with one or both cheeks red; the skin is hot, and the little patient is irritable and slarmed; the rough is louder, more barking, and resembles croup; the respiration is not quickened in proportion to the pulse, the also mai are not active, nor is the countrance anxious and distressed, as would be the case in preumonia or croup. On hoking into the throat no redness or change of any sort can be observed. As the disease creeps on, the child becomes prostrate, loses appetite, and

will not leave the nurse's arms or his down in bed. If you apply the car or stethescope between the scapular at the upper part, you may hear a little crackling at each inspiration, or sight rhouches; but the percussion-sound is clear throughout the chest, and the respiration is normal in all other parts. If these symptoms are not relieved, genuine bronchitis, promounds, or convulsions may supervens—conditions favored by the state of the atmosphere and the constitution of the patient.

So far as I have seen, the face never, at any period of the complaint, assumes that blaish tingo from imperfect aeration of the Road unless these croupfications arise. The physiological causes of this condition must be ascribed to pervous excitation; and in were roung children, we see how this may be set up. The tribecial perso, the pneumogastrie nerve, and the spinal nerves are all separately irritated and disturbed in their functions during the period of dentition, and in gastrie and intestinal disorder. Under the combined influence of cold, testhing, and gastrie disturbance, how easy of explanation are these laryngeal symptoms. Now eroup is the disease most likely to be confused with this affection, and when we are first consulted we may reasonably pause before committing ourselves to an opinion; but there are the following broad distinctions: If the child can talk, there is neither boarseness nor huskiness of voice; the fever is never high; the respiration not perceptibly hurried; the cough may be endden, convulsive, and ringing, but the crowing inspiration is absent, and there is not the restlessness and anxiety of group, nor is the larynx either torsler or apparently the seat of uneasiness. The cough and expiratory bark are the symptoms of all others that resemble croup; and, at an early stage, it is difficult to decide on the disease that may be about to spring up; but when twenty-four or thirty hours have clapsed, we shall have very little-difficulty. When this condition has lasted a few days, the child being one day better and another worse, you may almost with certainty give a favorable prognosis of the termination. As a rule, the presureory stage of crosp does not last beyond a day or two; the hourse voice and catarrial symptoms being rapidly succeeded by more marked and decided proofs of a dangerous disease.

As to the treatment of these cases, first and foremost is a warm, moist, and equable temperature, not lower than 60° Fahr., or above 70°. In the sente stage of genuine croup, it might be necessary to mise the temperature of the apartment higher than this. The cases under consideration are less acute and threatening, and it is therefore uncessary that surrounding influences should not be too exhausting. If there is a choice of an apartment it should be large and airy, and candles should be used in preference to gas and lamps. On many occasions I have noticed two large gas-harpers in small, low unrecries at the top of the house, where one or two children with their nurse are living through the day; so that the allowance of oxygen for each person must be very limited, and calculated to impair the general health, and to keep up rather than suldne the tracked irritation. On removing such patients to larger and better-centilated apartments they have speedily improved; but it is recovery to maintain a moist atmosphere, and for this purpose it is an excellent plan to place a flat kettle on the fire, with a long tube projecting above the guard of the fireplace into the room. At the end of the tube should be a transverse top, perforated with holes, like a garden flower-pot, to allow the steam to escape gradually. Such kettles are sold by Swan Nash, in Oxford Street, under the name of "Bronchitis Kettles;" in all cases of croup and laryageal irritation they will be found of great value. Where they are not obtainable, an ordinary kettle of water should be kept boiling on the fire; and even a hot brick or fire-ball should be thrown into a pan of hot water. This keeps up warmth and moisture in the room, and som exerts a soothing effect on the irritable membrane. When the symptoms are urgent and the cough distrooing, a sponge wrong out of hot water and kept constantly applied to the throat will give reisel. Unless the management be earefully looked after, the nurse is upt to make the child's ciothes wet, and even to neglect the application. I therefore usually onploy a piece of rag wetted in topid water, and apply it round the threat under oil-silk. This is both a convenient and good remedy. Mustard and vinegar poultiers to the threat, strong liniments, and other applications of a stimulating character distress and irritate the child, and are not to be thought of. If, as will generally be found, the stomach and bourds are not satisfactorily perferning their functions, we should lose no time in applying saitable treatment. The motions are often seasity and light-colored, sometimes containing undigested articles of food; sometimes of a greenish line and highly offensive. A grain of calomel, if the child is from one to two years old, with two grains of jalapin and two of white

anger, will be necessary, and this will smally stir up the liver and small intestines; after a free action of the bowels the breathing will improve. In some cases I have seen, the breathing has been good in the morning and the child has appeared lively, and even played with his toys; but towards the afternoon and stuning, rough has come on, and he has been more than once sick in the attempt to dislodge a little glairy mucus from the larynx. Succeeding in this, the child has gone on again comparatively well. as in whooping-cough, till the returning sparm and vomiting, But in most cases the discomfort is aggravated towards evening. and he passes a rostless night, getting no sleep from the irritating cough. Under those circumstances, it is a good plan to give an emotical boltime; say thirty drops of iperarmanta wine in an equal quantity of simple syrup. This will usually cause vocaiting, and if not, it may be repeated in ten minutes, or even a larger dose given; but this is sufficient in most cases, and the child is not depressed by it. A saline and disphoretic mixture, with two or three minims of ipersonanha wine, and the same quantity of the compound tineture of camphor, will relieve the cough and calm the nervous system.

When the more neute symptoms have subsided, a grain or two of bromide of potassium may be added to each dose of the mixture with advantage. Where the cough is very irksome, a teaspoonful of a mixture composed of equal parts of aromatic ayrup of sensa, symp of poppies, and syrup of squills, is worth giving occasionally. I sometimes substitute the syrup of backthorn for the semia. This generally opens the bowels, and saves the necessity for more active medicine. Delelity, pullor of face, and a wasted and wan look overtake the child when shut up in one room long together; and this is soon accompanied by a thick white far on the back of the tongue, darkness under the eyes, and tremulous pulse. A grain of the carbonate of ammonla should be given at this stage, with a few drops of ayrup of Toin, under the influence of which the tongue cicars and the child resumes his liveliness; to this should be added a few drops of the tincture of cinchons. The child may now be brought downstairs into a large room, and gradually prepared to he taken out of doors. Throughout an illness of this kind it is most important to support the hodily strength with beef ten, real or chicken broth, milk, thin arrow root and water, to which a third part of milk is added, or a little isingless in milk and water.

CHAPTER XXIX.

CROUP (LARYSON-TRACERAL DEPREBRISA OF SOME WRITERS).

PARROLOGY: Notice of the condition—Too satisfies of crosp—L. The message of obsried—2. The fibriums or informatory—Symptoms, course, and progress of such from — Harbid approximate—Classed observation of lens or lypical crosp—Diagnost from Systellaria and large-glosse—Treatment by the report both and question—Billianay— Harrony—Armits—Treatments.

Among the diseases of young children croup occupies a forement position from the occasional anddenness of its accession, the rapidity of its course, and the danger attending its termination. Parents readily recognize the first symptoms and are at once alarmed, and the child itself seen becomes terrified to a degree rarely seen in any other disease.

True croup consists in an inflammatory condition of the mosess membrane of the laryax and trackes, with the exudation of plastic lymph, which is quickly transformed into a firm adhesive membrane.

The inflammation has a tendency to seriously impede the functions of respiration by extending down the air passages and producing trouble-some and dangerous inflammatory complications in the lungs. The disease is generally acknowledged to be more frequent among male than female children. In my own experience three-fourths of all the cases that have come under my notice have happened to males.

The varieties of croup enumerated by different authors are not clearly to be recognized in practice. We may fairly speak of two varieties: 1. The autous or caterrial. 2. The fibricous or infermentary (croupous membrane), according to the predominance of certain symptoms. The disease is modified by the age and constitution of the child, and spasm or inflammation may be more severe in one case than in another.

 The cates real or moreus form is attended with hyperensis of the mucous membrane, followed by excess of secretion and dysprea. The symptoms may be slow and incidious in some cases, and the catarrh and cough, which precede the stage of development, excite no alarm till the hourse voice and ringing cough announce the true character of the affection. In some instances we learn that the child has always had a delicate chest, that any exposure to damp chorn, 323

weather brings on cold and cough, or it may be traceable to broschiris. The temperature in those cases rurely exceeds 101°. Such a history is favorable to an attack of emop in a young child. In another case the symptoms are more sudden in their accession. Deficate young children are sometimes seized whilst playing. one case that came under my observation, a boy, at. 8, left his play at 4 g.m., complaining of an uncomfortable feeling in his throat, and before six knors had elapsed the symptoms were severe and dangerous. In another case, a strong and healthy child, act. 21, was seized with croupal symptoms at 11 A.R. and in eight hours afterwards they had attained alarming severity. Her purents assured me that she had slept well, and was very brisk and lively till the attack came on. In these cases laryngitis would seem to berin at once. Still it will be found, with few exceptions, that some estarrhal and feverish symptoms had been present a day or two previous to the attack of croup. If an active smetic be given at this stage the breathing may rapidly improve, though the symptons may recur and require similar treatment in the course of a few hours. In the majority of cases the following day will see the child in a fair way of recovery.

2. Fibrinary crapp (tourked-syngilis-crospore or membrinary) is the typical variety of the affection in its neverest form. This is a more sente or intense inflammation; it is a true tracheitis, with exudation of plastic material, because the inflammation affects not only the muzous membrane but the fibrous tissue beneath. I will describe the course of the disease according to my own personal reservation. It generally begins with hearseness of voice and a peculiar harsh and ringing cough, because there is absolutely to secretion; for the same reason there is a sense of constriction in the tracken. The respiration is hurried, and the inspiratory effort is long and crowing. In some cases a few hours will being about the most severe symptoms; the pomum Adama may le even thing and falling very conspicuously with respiration; the eyes become swollen and bloodshot, the fips dusky, and the alse and artive; the skin is hot and dey, and the pulse small, hard, and rapid. Unlike the variety which has just been discribed, the temperature may reach 163° or more. The child may put his hand to his throat, and, in a deep hourse voice, say or express that he cannot fetch his breath. At this stage the percussion-note is dear over the thorax, the respiratory murmur is much diminished

throughout the chest, and a bond sonorous rile attends it. No moist sounds have as yet been heard. As the case goes on the eroupal exudation becomes more organized and clings to the larvax. when, if the case progresses favoraldy, either the rust is through off or resolution ensues with absorption. If the disease is extending, inspiration is now greatly impeded from blocking of the tracker by the false membrane; there may also be a tough piece of lymph in the trackes which cannot be disledged. The laryux and nes-oles of the neck are very active. Notwithstanding the laborious and painful respiration the child may, nevertheless, sleep soundly, though waking occasionally in terror. Thirst is generally present. and swallowing may be painful, but I have known a child drink a large cap of milk half an hour before death. Still, any attempt at deglurition is generally painful and brings on the cough. The pulse now becomes small and weak, and reaches 100; the crowing and hissing sounds in respiration increase, and the cough is lacessant and painful. When the symptoms have attained this intensity, sycovery is rare; the voice falls to a whisper, or departs altogether, and the cough is weak and sufficating. Sometimes, even at this stage of strangulation, shreds of lymph and false membrane are expelled by a violent offert and paroxyam of soughlug; but the relief is only temporary, and the ageny of oppressed legathing sion returns. The countenance now betrays the most poinful anxiety; it is bloated and distressed, the tongue and lips are dusky, and the forehead and surface of the body are bathed in strent. The pulse becomes feeble and threndlike, occasionally intermitting, or falling in frequency. The child is restless, and constantly turning about for rollef, throwing the bend back against the spine, or from side to side, while the fingers are best in the palms of the hard. Agony is depicted in every feature. The struggle for breath goes on till the little sufferer dies convulsed, or passes into a state of stupor from which it never wakes again. A case that came under my notice illustrates the sublen fatale termination not infrequent in this disease. The child, es. 5, had been going on well for two days, and was sitting up in bel playing with her toys, and breathing tranquilly. In the night the respiration became embarrassed, and she died asphyxiated twelve hours from the period of relapse. After death a thin piece of partially detached enought exudation was found lodged in the

encer. 325

glottis, and this caused the fatal symptoms by occluding the largest.

The false membrane found lining the air-passages varies in ex. tent; in one of my cases I found, on opening the larvax and tracken, three long and narrow pieces of lymph, one apwards of two inches in length, and the others nearly as long, between the lower horder of the cricoid carrilage and the last rings of the traches, without any extension to the bronchi. In this case moist sounds trens heard in the chest on the second day of the Elness; but they had disappeared on the fourth and fatal day. Near the level of the upper horder of the cricoid cartilage were to be seen small tough fragments of lymph, not readily detached from the surface beneath. The mucous membrane was everywhere red, and in places vividly so; but there was not any evidence of submucous offusion, for it must be remembered that the connective tissue of the laryex is very small in quantity. In other cases, lymph may be observed throughout the tracken, and the mucons membrane may be pale, except in isolated patches, where it is red and vascular. The false membrane varies much in frem and consistency; sometimes it is ovlindrical in shape, and loose, or adherent to the mucous numberane beneath, from which it is not readily separated; in other instances it is moulded to the shape of the broughial tubes, where the inflammation has extended into the lungs, and in these cases the effects of vomiting fail to bring away the source of irritation, and the danger to life is therely increased. When the false membrane is loose and fragile, it is casier of expectoration; and it is these cases that have the best thanco of recovery, particularly if limited to the laryex and traches, the lungs not being involved in the inflammatory process.

Of late so much difference of opinion has arised on the pathology of croup that we are induced to ask what is understood by the term?! Until recently it has generally been regarded as a local disease, an inflammation of the trackes attended with the formation of false membrane (crosspal exudation), though the practical physician most commonly recognizes the disease by the spasmodic closure of the glottis, the prolonged and crowing inspiration, and

^{*} The result of the discussion on manufactures errors and disjutched at the Royal Medical and Chicagonal Society in 1875 was, that membraneous larguagitis may arise from measure lughamentism, or in resuscetion with specific disorders of various kinds, but that the most frequent cause is disjutched.

the fear of impending sufficiation. If to these symptoms are added fever and inflammatory excitement, he has no doubt whatever that he is dealing with a case of genuine typical enup, such as had been known before diphtheria was recognized and distinguished in this country. To me it appears that croup, whether simple or membranous, is a totally different discuss from diphtheria, and that they only approach any degree of relatiouship when the latter discuse has incruded the largues, and then the symptoms due to obstructed breathing are much the same in both cases.

We constantly meet with genuine eroup of an acute and local inflammatory character, leading to the well-known false membrane in the tracker and laryux, as described by the old-fashioned authorities. It seems impossible that we can mistake this true crosp (which we have been in the habit of meeting with all one lives) for the peculiar membranous inflammation of the tracker sometimes seen in cases of dipletheria. It is not to glance at some remarkable points of difference in the two affections.

- True crosp is prone to attack the healthlest children, and in districts where diplotheria does not prevail."
- True croup is upt to come on very suddenly, and in cases of recovery the general health is rapidly re-established, as compared with diphtheria.
 - 3. In diphtheritic croup the discuse is of a well-marked conti-

There are many instances on record of a whole firmity of children dying of supertherea in the course of twenty or therety days. Malagorat epidemics of this terms have prevailed in this country street 1851; but we have record known of there are of genuine strong happening at one and the same time as a single family, and as how notice known them but so long. The recurrence of diphtheria is the same hour has been noticed oper and core again, and traced to had drawing, previous that the power of countgion larks and linguist about, ready to miss as the previous four-roof in health or exceptible to its influence. The disease is not present a smark delicate children where traces are builty tracitions, and a here entirely posterations are neglected.

It would be impossible for the want of space is easer here into the long and cerell question as its winther the cross of Bonas and Chayne in this country is the same disease as the "diphelicrite" of Bonas seam. I can discover making it wissum this conclution, see, if identical, seedy modern entires would have had their standing diseased to the resemblence in the course of long and varied experience. Diphelicrite is a disease only recently described with precision; in some as attention was diseased in its physicisms at once recognized a near disease, both in an assumpted and clinical features, entirely different from anything they had previously near and powering symptoms at complete variance with the averaged inflammatory or true comp-

CHOUP. 327

tutional character, and is always accompanied by great depression and acryous symptoms.

- Croup is a local disease; diphtheria is a constitutional affection, in which the kidneys and intestines may be involved. Uroup is aeither infectious nor contagious; diphtheria is both.
- 5. The cases that recover from diphtheritic cross are few, and the convalencement is not only very slow and tedious, but the threat affection is usually proceded by a characteristic membrane on the palate, and the prestration is always great. Partial loss of voice, fetial breath, ewellen neck and glands, dimination of muscular power, paralysis of the muscles of deglutition, and albuminumia are common in diphtheria; but they are not witnessed in inflammatory cross.
- 6. Between croup and diphtherix there is also another very important diagnostic difference; diphtheria generally begins in the plaryns, aroup in the larynx." The false membrane found in the larynx in cases of genuine croup is quite different from the leathery or yellowlah-gray exudation found on the tonsils, in the heyex, and brenchial tubes in cases of diphtheria. The pathological differcares between croup and diphtheria are open to further contrast. In the early stage of eroup there is an increase in the enscularity of the affected membrane, as in severe catarrh, with a trifling amount of inflammatore explation. This is succeeded by fibrillation of the exaded lymph, which, with the new-formed cellular elements, becomes transformed into the characteristic faint manboses. Its consistence varies, being in some cases tough, in others soft and amorphous, and easily removed from the mucous membrane beneath. In the larynx and upper part of the tracken, where the inflammation is most acute, the explation is croupal or membranous, and is very characteristic of true croup, but in the lowest part of the traches and diverging brouchi, there may be nothing more than a scanty superficial layer of mucus.

[&]quot;My bles of the problem to be solved to, in fact, this, It must be allevited that the diphthesitic pairwa is capable of giving nise to a photoconformation of the beyon, apart has the existence of any similar affection of the photyen. One there is good massa to believe that during spacement of diphthesia the cases is which this section are in the highest degree exceptional. If, therefore, it can be shown that in the practice of a present temperature of a present temperature of a present temperature of a proportion to the total number of cases of alphanesia, there will be a strong probability that the aniposity of the former cases are dependent upon some other cases that the diphthesitic points."—Diphthesia and Charp, by W. H. Lamb, M.B., and C. Hilton-Fagg, M.D., Gag's Hospital Reports, 1877, p. 245.

"It is difficult in many cases to draw any line of demoration between the histological changes occurring in diphtheria and those of croup. In diphtheria, however, the submucous tissue usually becomes more extensively involved, so that the false mondrane is much less readily removed. The circulation also often becomes so much interfered with that portions of the tissue lose their vitality, and large ash-colored sloughs are formed, which, after removal, leave a considerable loss of substance."

7. If aroup were identical with diphtheria, it seems to me that the operation of tracked only would rarely succeed; whereas it is often successful when false membrane has blocked up the tracked tube, and has been removed from time to time after the operation.

The following affords an excellent illustration of the conqueson between croup and dightheria.

Dr. Sansom has related a case of pharengo-laryngeal diphtheria with alleaminuria, in a female child four and a half years rid, where trackectomy was resorted to on account of dyspace and embarrassed breathing. White patches were observed on the phary ax and right tousil. The edges of the wound were covered with diphtheritic false membrane, and eloughing proceeded, accompunied with extreme prestration. A wound of the ring finger of the right hand was covered by false membrane, and from this wound ulceration extended, and involved a part of the right hand. During the following week there was little change, then extreme advannia susped, preumonia attacked the bases of both lungs, and the shild died sixteen days after the operation of tracheotomy. After death the largux was covered with false membrane, the fissnes around the tracked wound were infiltrated, and there was sloughing of the soft structures. The kidneys were in a state of gonte nephritis, and the lungs showed diffused beonehooneumonia."

The treatment that would put an end to catarrhal croup would hourly aggravate a case of diphtheria and hasten death. This alone is sufficient to convince us that the two diseases are seentially different. A child is put to led in an atmosphere of stransuffering from neute croup, and after the action of tartar energy and perhaps a grain of calonel, the alarming symptoms gradually subside. This is never seen in a case of diphtheria; the nerveus

Pariology and Merkid Amazons, by T. H. Owen, M.D., 34 edition, 1975, p. 365.
 Coorp and Depictoria: a Contrast. Med. Soc. Proc., vol. 65, 1975-77, p. 495.

CROUP. 329

presentation which invariably accompanies it would be aggravated, and life probably sacrificed, by the adoption of such treatment.

Largesylvanus stridates is another disease which is aps to be mistaken for eroup; but the following diagnostic points of difference are as bread and clear that in ordinary and well-developed cases it would be inexcusable to confuse them;

Laryngistous usually sets in suddenly with alarming symptoms, and terminates abruptly; in true eroup the investor is less sudden, there has been cough and febrile disturbance for a day or two, and the symptoms, instead of declining, go on increasing in security.

In a typical case of largengismus the voice is unaffected, and there is no cough; in croup there is both cough and change of voice, and the latter is often weak and feelels from the commencement.

% In lagragismus there is no expectoration nor any entarrhal sounds in the chest; in croup such symptoms are constantly met with.

4. In laryngismus there is no fever (that is, sufficient rise of temperature to deserve the name of fever), and the circulation is undisturbed, except during the paroxysma; in eroop the fever runs very high, there is thirst, heat of skin, and quick pulse.

5. Age comes greatly to our aid. Largugiouse is most common in infants during dentition; croup is most frequent between the

second and fifth years.

6. Laryngismus is most common among stramous and rickety rhildren, and those who have been alling and out of health. It is constantly associated with dentition, and overfeeding or improper food; croup often attacks the healthiest and strongest children, and generally arises from exposure to cold winds, or damp; it is far more frequently fatal than laryngismus, which is only exceptionally dangerous.

7. In croup there is not the same immediate violent struggling for breath as in laryngismus; then, too, in laryngismus there is

complete recovery between the paroxysms.

8 In larguagismus the condition is one rather of synoops or fainting; the attacks are usually too short to produce permanent lividity from imperfect negation of the blood.

 In laryngismus death may occur from complete asphyxia; in group a sudden termination may result from a portion of detached false membrane exciting fatal spasm of the larynx; but death usually happens from interrupted respiration and circulation through the lungs, with gradual degression of the vital powers.

19. In a case of laryngiamus the inspiratory effort is temporarily affected, arrested, or even stopped entirely; whilst in crosp, the embarraneed breathing is permanent, and expiration as well as inspiration are both involved.

 The treatment of the two affections is diametrically opposed; the remedies that would relieve the one would aggravate the other.

So much for the distinctions of laryngismus from croup. But I must not discuss this question of diagnosis without admitting that there are complicated or mixed cases, attended with whereing and catarrhal symptoms, where a degree of catarrhal infammation is mixed up with the spasmodic affection. These are the cases which more nearly resemble true croup, cases of medicial laryngiamus happening to young children, where we have nasuch procise landmarks as these I have attempted to define. Ther commence with slight catarah (colsected largegilis), hourse and noisy cough a day or two before the characteristic growing inspiration, and they sometimes procede an attack of postmonia or measles. It is eases of this kind, attended with a cromy cough, which are upt to deceive and mislead us; there is, in fact, some swelling and inflammatory action of the larguer and vocal cords added to the original spasmedic affection. The presence of cough, with wheezing and dyspons, might induce even a practiced observer to think he was dealing with an ordinary case of crosp, but as it advances he is able to satisfy himself that genuine space. is at the root of the svil. In the simplest forms of catarrh in some young children, the voice is hourse and the cough barking. To such an extent does this prevail, that a diagnosis is not tavariably easy at the beginning of an illness. The mucous membrane of the larynx is highly irritable and sensitive, and readily become inflamed and swollen on exposure to cold air. This is probably the condition that is present in those cases of laryngismus attended with incessant and eroupy cough. Though we must not expect to find the same pathological change, or the same catalogue of symptoms, in all cases of laryngismus, still, viewing these cases from what point of view we may, I can solden imagine any real difficulty to obscure the diagnosis of these two affections, if we

331 CHOOP.

hear in mind that in genuine hayagianass the largus and tracker are free from inflammation, that the attacks are sudden and temporary, that there is no cough and no fever; all which symptome are the accompaniments of croup.

Of the forms of croup, there is: 1. The catarrhal croup, a mild class of cases of frequent occurrence, which rarely places the life of the patient in imminent danger. It may come on in the night, with some heat of skin, frequent husky cough, quick pulse, and fushed face; and for a few bours the symptoms are severe and alarming to the parents; even the medical astendant is doubtful about the issue of the ense; but after a dose of calonal and the free action of an emetic (the room being kept moist, and its termperature high), the symptoms soon decline, and the child is hinself again, with the exception of being a little prostrate and pullid.

2. The Ebrinsus excep or trackettis, happening to healthy children, which comes on suddenly and is attended throughout with flanger. These cases are rapid in their onset, and are quickly fatal.

The tendency to a recurrence of croup in some children is a favorable sign so far as regards its severity; such cases soldons terminate fatally, for these are of the orthodol form. If we are told that the child has had one or two previous attacks, we may generally regard the case as satisfactory. Such cases stop short of artial explation, and spassa also plays an important part in the production of the symptoms. The narcous membrane of the laryers and tracken is in a state of inflammatory excitement, and the vessels are full and congested. Prempt treatment rapidly unloads the distended vessels and encourages expectoration. Intelligent mothers, whose children are so attacked, come at last to view the symptoms with little or no anxiety, feeling confident that a good fire, with a steaming kettle in the room, a brisle smetle, and hot sponges kept constantly applied to the throat, will seen being the child round. The lesson to be learnt here, as a every other variety of croup, is to lose no time, for mocess in treatment depends on meeting the symptoms with promptitude. Above all, care must be taken not to confound these cases with laryngismus, for in the one there is forer and presistent difficult breatling, whilst in the other there is no fever, and the breathing between the puroxysms is calm and tranquil.

Treatment.—Careful study of the disease has done much to instruct the medical attendant, and the knowledge that no time is to be lost is so commonly aprend, that before we are summered to give relief some useful measures have been tried, and thus many lives are saved which neglect would have repleted hypotens; yet for all this it is estimated, according to the returns of the Registers-General, that about 6000 children die annually of croup in the United Kingdom, a mortality which ought to eallighten as as to its fatal mature, and induce us to study the less method of dealing with it.

I have observed nothing of late years to induce me materially to alter my opinion from the following conclusions, at which I arrived in 1863.

1. The temperature of the room should not be lower than 63%

The vapor-bath is indispensable in the treatment of cropp, and should be used at the commencement in every case, and continued noremittingly until all fear of a relapse has departed.

All cases of croup are invariably relieved by the experiath, especially if the tracheal membrane is dry; when it is moist there might be fear of causing too much depression.

 The carlier that a case comes under treatment the greater the probability of a successful termination, because it is then possible to prevent the tracheal secretion becoming organized.

5. The most trying difficulty we have to contend with in the unmagement of croup in the catarrhal form is a relapse, because with it comes exhaustion; and the weaker the patient the less will be the chance of recovery.

 Tarturated antimony is our sheet-anchor as a medicinal agent, not so much from any specific effect it exerts on the trached membrane as from its certainty in effecting free and speak routting.

7. When the emetic has fully operated, if there he much febrile excitement and disordered prime vie, which aggravate the large-goal symptoms, a grain of calconol every four hours, or one fall does for the purpose of emptying the howels and controlling the fever will be found necessary. In the fibrinous form, when there is violent and acute inflammation, with a firm hard pulse, and a full reserve of strength, two or three larches may be applied over the thyroid cartilage, and bleeding can easily be arrested by pressure with the finger, and if need he with cotton-wool; then necessare with the finger, and if need he with cotton-wool;

canup, 333

cury may prove a valuable addition to the antimonial treatment.

Some of my cases improved from the moment the mercury affected
the bowels, the fever diminishing, and the expectoration of the
false membrane being promoted. When employed in small doses
at regular intervals, it would appear to diminish the cohesive attachment to the nuncous membrane, and to render the lymph bass
fibrinous and more readily absorbed.

8. When in a case of crossp, seen at an early stage, and satisfactorily progressing, forty-eight bours have clapsed, we may generally angur a favorable termination; and we should then begin, if not before, to support our patients with good beef ten, milk, and arrowrost, and (it may be; a little wine and water.

If after vomiting the temperature remains high, and especially when the bourds have noted freely, minim doses of aconite every two or three bours are of great service in inflammatory croup. This keeps up a gentle dispheretic action on the skin, diminishes tension of the pulse, and controls vascular excitement in a very striking manner. At this stage it comes in well, because antimony should not be long continued in any of the diseases of children, and it certainly ought not to be in this disorder.

On the question of trackettony, I am inclined to think we may urge a great deal in its favor." When the respiration is so involved as to produce almost complete unconsciousness, swelling and distension of the features, and lividity of the lips (convulsive efforts that indicate approaching suffication), we should cling to the chance it holds out. When all remedies have failed to improve the patient's condition, and death is near at hand, we should not let the patient die without giving him the chance of life which an operation affords.

In most of the cases of tracheotomy that have fallen under my notice I have almost invariably observed an improvement for a time in the respiration, and the fact that a few days have been gained when death must have terminated in as many hours is a great point in favor of the operation, and for not delaying it too long. If tracheotomy is to succeed, it must be done before the strength is quite exhausted and asphyxia has thoroughly set in.

M. E. Dudon, of the Höpital St. André, Bordeaux, performed the operation in twelve cases, with six recoveries; and he is of opinion that could be have performed the operation cardier in some of the

^{*} See the squarks on tracheology in the next chapter.

other cases he would have had more recoveries. When medical means have failed, and the largue is invaded by false membranes, which cannot be got rid of by vomiting or other means, M. Dudon thinks tracheotomy justifiable."

It should be our carment endeavor to recognize whether we are dealing with the catarrhal or the fibrinous form of crosp. If we are convinced it is the fibrinous form, then it must be at the discretion of the surgeon whether or not the symptoms are such as to lead him to expect that resolution will take place. If not, tracksocomy should be performed at once, as its postponement would reader a successful issue less probable.

Trackentomy in itself is not a dangerous operation, but if it he delayed till the lining membrane of the larynx and tracken are covered with false membrane, extending as far as the primary divisions of the bronchi, and the constitutional symptoms are becoming severe, the chances of its success are materially diminished. This we often see when trackentomy has been performed at too late a period of the disease, and the operation has the discredit of the fatal result.

When extensive, or loose, or purulent portions of false membrane occupy the primary branches of the broachi, and extend to and shoke up the smaller or minute breachi, the operation cannot be expected to succeed. It is frequently performed as a last resource, when the respiration is imposed and embarrassed, and exhaustion has advanced too far. Under a combination of asphysis and authenia the child sinks.

In those children who survive the operation for some days, bronchitis, precumonia, bronchopneumonia, and convulsions are the most frequent causes of death. A tendency to pulmonary excitement already exists, and indeed the operation itself is calculated to originate it. Tracheotomy is a very successful operation when performed for the relief of chronic laryngeal diseases, or for the removal of foreign bodies from the nir-pusages. But it is algorithm that this operation does not generally yield satisfactory results when undertaken in cases of edema of the glottis, occurring in children who have sucked boiling water from the spouls of kettles. After this grave accident, lung affections very often supervene, from the inspiration of scalding vapor simultaneously with the boiling fluid. Tracheotomy aggravates the pulmonary

^{*} The Laucet, July 20th, 1872.

споср. 215

complication; yet it must be done, on account of the edema of the glottle. Very similar considerations apply to crosp. In some cases where children have been saved from the prospect of immediate death by trachestomy, and the capula cannot be removed with safety for a moment without the danger of asphyxia, the chances of ultimate recovery are very slight. The little patient, having rallied from the operation, goes on satisfactorily for some days, when it becomes restless and faverish at night, with a hot skin and a quick pulse. If we auscultate the clast, we find extentive bronchitis, and perhaps some pneumonia. No more sputa are evacuated through the canula, and the child soon becomes convalued, or dies in a comatose condition. There may be no accumulation of false membrane in the larynx; but if the glottis is nearly closed by swelling and extense, and the mucons membrane injected and vascular, the extension of inflammation down the traches and brought into the tissue of the long is almost certain to eneme. If the case goes on, alsons of a portion of the lung, plenrisy, or empyema are among the morbid changes discovered after death. From all I have been able to ascortain, the operation of trachestomy is loss likely to assemed in children under two years of age than in those above it. The tracker is small and undereloped, it is not so easily reached as in older children, and harmorrhage may ocour, but a competent surgeon may readily overcome it. Yet in the face of these difficulties infants have survived the operation; but the greatest number of recoveries has occurred between the ages of five and six years.

It has been alleged that the direct admission of air to the lungs without having previously passed through the mouth and nasal passages, is attended with real danger, and that congestion of the lungs is another danger induced by the operation. But seeing that the temperature of the room can be raised to any extent, and that appliances for the supply of warm moist air are to be prorured, congestion of the lungs from this cause alone ought not to occur.

DIFFIGURE AND ASSESSED OF THE STATE OF THE S

Evidence of the antiquity of the disease is to be found in the writings of Hippocrates, Celeus, Arctseus, Galen, and Codius Anrelianus. In more modern thues, descriptions of it are given by Spanish, Italian, French, and English writers, and traces of its progress have been met with in America, Africa, and Hindestan. It prevailed in Helland in the sixteenth century. By some writers it is thought to be the same disease that was known a bunded years ago under the name of spidencic croup and malignant sore throat." It made its appearance at Tours, in France, in 1818.

^{*} Tie. Furthergell's account of the term throat attended with alone, 1748.

This discuss, until the last few years, has been confounded with erystpelus and scarlet fever during their epidemic prevalence. The credit belongs to Bretonneau of being the first writer to define its exact nature, and to show that the local appearances on the throat and fauces are the manifestations of a general and constitutional discoder.

Since the beginning of this century, cases of diphtheria have been recorded from time to time by English physicians. In the years 1858 and 1859 the epidemic attained its maximum in this country, and in two years about 20,000 persons fell victims to it."

Symptons.-The incubation period is usually very short. " Acesteding to Oortols, the latest and best writer upon the disease, it may be stated positively to occupy from two to five days. His own experiments also show that in from twelve to twenty-four hours after artificial inoculation upon the surface of wounds, we can detect a grayish-white discoloration, a dirty-grayish layer, and the other signs of infection. 7 Dr. Morell Markengie has given an instance of a prolonged period of incubation, lifteen days clapsing from the exposure to contagion to the appearance of dightheria! The disease energs on very insidiously, and may have advanced considerably before any complaint is made about the threat. The surfices symptoms are chilliness, weakness, and hasitude, with pain in the back and limbs, followed by febrile disturbance of varying duration. In some severe cases the fever is transient and soon passes off, but in mild enses it is of longer duration. Elevation of temperature generally marks the comnancement of the disease, it may soon reach 103" or 104", when delirium is often present; but in many cases the temperature appears to fall as the disease advances, the skin becoming cold, and the palse slow. These symptoms often precede death. Thereis beschrifts, thirst, and pollor of the face; the sleep is restless and meany, the mental faculties are clouded or excited; the pulse is almost always quick at the beginning of the complaint, and soon becomes weak and compressible. Cases are recorded of unusual howness of the pulso, and Dr. Heslop mentions one in a child of five years of age, where it did not exceed forty leats a minute.

I Article Diphtheria, Zimmson's Cockepedia of Medicine, vol. 5, p. 201. Quoted by Vertices, Clin. Trees, 1818, p. 248.

¹ On Exphilherin, 1879, p. 19.

The tongue is covered with a thin, creamy fur, or it is quite clean except at the posterior part. The appetite for food is small, and the prestration of strength so great that the patient is two weak to exert himself to take food, and consequently many patients die, who reasonably might be expected to recover if they could take a

repper amount of mourishment.

The urine is pale; it contains urates or even phosphates, and at an early stage alliamen is frequently found. Albuminuria is one of the most interesting features of the disease. Attention was first drawn to this symptom by Dr. Wade, of Birmingham." It generally appears at an early period of the disease. It is a frequent complication of diphtheria, and increases the danger to life. Whether albumen is present in large or in small quantity, it is a serious symptom. But albumen bears no relation to the other symptoms, as it is equally present in mild as in server cases. Cases of the urinary tubes do not invariably accompany the most profuse albuminuria,† and the albumen may disappear altogether in the course of a few days, as the approach of convalences is reached. Greenhow remarks that he has " several times been mable to detect albumen by the proper texts in very malignant cases of diphtheria."

On looking into the throat, some reduces or swelling may be observed on the faures, pharynx, and tonsils; the cervical glands are enlarged; there is pain in degintition, and stiffness of the neck in separating the jaws. The eyes have a heavy, languid look, and the conjunctival vessels are injected; the nostrils are inflamed, or obstructed from swelling of the Schneiderian membrane. or the presence of a tenerious secretion. Between the first and second shay from the communication of the throat symptoms, the tensils become more swollen, and a fibrinous explation can be sem coating them, as well as on the back of the placerny, which is now turgid, and assumes a claret buy. Over a part of the inflamed surface, a tough layer of gray-looking lymph is deposited, resembling wetted classo's leather or damp purchment, which continues to increase in thickness; in some instances it is very thin and superficial. This false occubeane (which is pathognomonic of the disease) is not invariably of the same color; in some cases it presents

⁵ Midhad Quarterly Journal of the Medical Sciences, 1888.

[†] Greentow on Diphtheria, p. 264.

¹ this, p. 207.

a dirty white or yellowish appearance; in others it is of a brownish or ash-colored bue, and in exceptional cases it has a blackish, gangrensus look, and is horribly offensive." In some cases the explation is first seen on the soft palate, or on one or both tomils, but wherever it may be, it either extends from one part to mother, or it simultaneously appears on several parts at the same time, Spots of exudation, which at first are separate and distinct, will enalesce and form a continuous layer in a few hours. The extent and color of the explation are generally in proportion to the severity of the disease. When there is a light and small distinct. patch the disease is mild and runs a favorable course; but when the exudation is extensive or thick, or the patches units or form a continuous layer, then the constitutional depression is great, and the patient is in imminent danger of his life. In some cases cough is a very early symptom. In June, 1869, a loy, aged six years, presented himself in the out-patient department of the Samaritan Hospital, whose illness began with a slight cough on the 5th. On the 8th, when he came under notice, he had a hearse and frequent cough, and his voice was subdued and husky. On the lower part of the pharynx and right toneil was the characteristic membrane; the child was very weak and pallid, the tengue coated, and the pulse 140 and forble. He made a good recovery, the only sequelse being anlargement of the tonsils.

When the exudation has fully formed, it mingles with the secretion from the murous follicles, and the cervical and submaxillary glands become entarged, and the whole neck swells. The shift is now much distressed, as there is great pain in swallowing, and the poissons secretion excerince the mouth and nostrils. As portions of the deposit separate from the threat and are coughed up, there

^{* &}quot;The diphtheritic possite membranes, or, to speak more precisely, the diphtheritic alongle, sends from superficial gaugeons of the unicess membrane, which again depends as compression of its national vessels by an incomital fibrinous condition, or less weeking of the tions consent, which are tilled with a cloudy enterince "—Nowwell Protect Medicine, vol. ii, p. 616.

Information is not essential to the discuss, according to some authorities; but this is a question which pathology sught to decide. Exploration is distinguished by a provider modald condition of the massive numbers of the threat and tombs. A sero-sense effection is possessed out on the back of the threat, which becomes changed into a tension members, followed by the formation of mother similar rescaleszons. For some, all a rough plants layer is produced. The false rescaleszon as the mixed form the surface, which is observed and blooding. The pellishe of bloomershouse is chiefly underly affiliational subhedison, congrabble lymph, yes, and blood-corposches.

is great feror of the breath, and cometimes bleeding from the mouth and nose. This explation is tough and fileinous and does not separate easily except where it is undergoing decomposition, When it has separated it leaves a smooth bleeding surface, on which the explation rapidly forms again. As the disease goes on, the respiration becomes impeded by the obstruction to the subrance of air through the larynx, producing diplotheritie eroup," and the breathing is croupy and stridulous. The voice is muffed or reduced to a whisper, and the eyes are staring and suffused. The vessels of the neck are distended, and at each inspiration the decression above and below the chivieles are sucked inwards, and the spigatrium is retrarted. With these alarming symptoms there are also pains in the head, which the child moves incessantly; the surface of the skin is cold and clammy, and there is extreme agitation and restlessness. The consciousness becomes more and more impaired, and the child dies sufficated and exhausted. Death onsus as in fatal cases of croup-from asphyxia.

When the pharyngeal affection is aemte and severe there is great
poin and difficulty in swallowing food, but as the disease advances
the sensibility becomes blunted, and there is no complaint of pain.
The patient sinks low in the bed on his back, and is insensible to
all that goes on around him, or be is delirious and mattering; the
impulse of the heart against the walls of the clost grows weaker,
not the pulse becomes feelile and imperceptible. In such cases
death ensues from asthenia or syncope. When laryngeal symptoms occur the patient may disc in the course of two days, but
when they are absent death may not impen for two or three
weeks. In cases that recover contains encounted by the British Molest
Journal, twenty-six died—fourteen from asthenia, eight from implication of the larynx, three from syncope, and one from subsequent broughitis "?

Cours.—A specific poison, either generated within the body or external to it, is the cause of diplatheria, which spreads by

Diplate-ritie result is some resource in some epidemics than in others. The desone stores no uniform disposition to attack the largest and tenches; using case have terminated through shore exhaustion, though them has been somes throat complettion and alonghing; while other cases, and even some epidemics, have been marked by the committee of the disease has the largest, and the apartons of every, with the throat and threes comparatively free.

[†] On Diphthuria, by Dr. Squire, up. sit., p. 129.

contagion and infection. Sir W. Jenner traces "diphtheria (like ervapolas) to cold when the exposed person is depressed from fatigue, mental or moral causes, etc." It spares no class of the community, affecting the poor as well as the rich, whom an epidemic prevails; but it is probable that, notwithstanding the evidence that has been brought forward to the contrary, defective drainings, debility, and exhaustion favor its development. The disease is not peculiar to any particular locality; it has been us prevalent in high and exposed situations as in for and sheltered places; on clay and damp soil and on dry and light soil; on richly guittivated soil and on barren moorland; in the open country and in the densest towns. It does not, however, appear to be so frequent in dry districts, where the drainage is good and the soil permeable, as in damp, marshy districts in the vicinity of water, Still this does not clear up the cause of the epidemic, for dry places lave been severely visited and damp places have escaped. "Indood, it is evident that some other factor besides damp is required for the exumption of this disease, seeing that humidity in every concrivable form and degree always exists in one place or another; whereas diphtheria had been unknown as an epidemic in this country for three-quarters of a century previous to its recent invasion. Dampness must, therefore, be regarded rather as an auxiliary than as a principal cause of the discuse."

As to the outbreak in North London, in 1878, Mr. W. H. Power found that, with regard to time, the customers of milk retailers who bought their milk of the same proprietor here aimset the whole of the brant of the outbarst, which first attracted attention to the district, and which was referred to sower causation. It seems probable that Mr. Power's observations must be regarded, in the present state of our knowledge, as rather suggestive and incitive than conclusive.

What the exact nature or essence of the discuss is we do not at present know. How the garms of the discuss are first developed, whether they ever arise of nose (which is not improbable, or whether the soil into which they have been introduced is psentiarly adapted for their growth, are questions which the science of multitive has still to deal with, but certain it is that when a person is struck down with the disease, he is capable of contaminating the

[&]quot; Remainstony Address below the Clinical Society, 1873.

⁷ De Greenhow on Diphtheria, p. 124.

surrounding air and drinking-water, and so of communicating the disorder to others.

Bretonneau held the view that the atmosphere could not trussnot the contagion of diphtheria. He mught that the only way in which it can be contracted is by inoculation—that the diphtheritie secretion must come in contact with "a soft or softened muces membrane, or with the skin on a point domaid of epidemis."

This is a subject still open to discussion, but most authorities agree that the discuss is contagious, and can be conveyed by the atmosphere, invisible emanations from the sick, or even from sever gas.

Family susceptibility is sometimes very great. All the members of one family may be attacked, whilst those of another family living under the same roof may escape. Some may have the disrate slightly, and others severely; the deheate seconds more readily than the strong.

A correspondent throws out the hypothesis that as the disease often spreads in a family, and does not extend to other persons going freely about the patients, "the poison germ of dightheria is modified by its habitat, becomes in fact a new variety growing out of and specially adapted to the constitution in which it has developed, and that this contagion finds in the kindred constitutions of brothers and sisters fit self for its growth, while it is thrown off by stranger organisms to which it is unadapted." Dr. Alford Carpenter also supposes "that diphtheria is dependent upon a germ of living matter, which is capable of reproducing itself when it meets with a congenial soil." He considers that there is a close analogy between it and potato hlight; the conditions which promote the one have also un influence upon the other. He adds that sulphurous acid, locally and generally applied, is the best applies then, and that the germs cannot grow in a crease atmosphere.

The clothes of a person may be infected with the poison, and he may thus transmit the disease to others, though he is not laboring under it himself.

An instance came under my notice in November, 1878, where a little boy in health called at a house in which a child was lying if

^{*} New Sed. Soc. Trans.

f On the Contagousness of Diphaltonia, the Limeat, Jun. 8th, 1879, p. 58.

¹ A Provide Predisposing Cause of Diphthoria, Brit Med. Journ., Jon. 4th, 1879.

of the disease; he returned home, was struck down with the discase within forty-eight hours, and died on the seventh day. He conveyed it to two brothers and a sister. The little girl, eight years of age, walked eight miles one day, was prostrate with the disease on the next day, and expected to die on the third or fourth day, but eventually recovered.

Sepuda. The heart is prone to become enfeebled, not withstanding the free exhibition of stimulants and the progress towards recovery. Sudden failuse of the pulse and circulation now and then comes on, and the weakness continues till death. Valvalar disease of the heart has been known to result from diphtheria. The procases involved in this disease may bring about morbid changes of the endocardium affecting the valves. Dr. Burdon Sandersons has shown the identity of the valeular lesions after diphtheria with the alcerative endocarditis of Kirkes, well known to result from several soute specific diseases. Sanderson continues by demonstrating what he happily terms the "doubly infective character" of those forms of endocarditis after neute diseases. They result from specific infection, and in turn produce morbid changes in the ergans. Infective material becomes detached from the diseased valves, and distributed to the kidneys, liver, and lungs. Heiberg and Waigert go further, and pretend to have discovered the very Jourst origo seeds in colonies of micrococci, which ther believe pro-4 ree the endocardial disease.

Sometimes the nessenlar system is fearfully depressed, and the patient loses all power over his limbs, so that he cannot support himself or put on his clothes.

Diptokritic Paralysis.—Authorities differ as to the nature of this paralysis, some regarding it as of reflex origin, and others as due to exhaustion of the corsbro-spinal centres. "The paralysis is more describing of the mane general than any other which I know, for all the physical powers are affected, and sometimes the mind is anfeelded."

‡

The affection generally comes on during convalescence from diphtheria. It appears to bear some resemblance to becomotor.

^{*} Lacrany on the Infective Processes of Diverses, Lact. IV, Brit. Med. Journ., Feb., 8th, 2878, p. 878.

t See Ongs. XLI, on Ultressive Endomnilios.

I Dinner of the Nervom System, by S. Willis, M.D. 1878, p. 234.

ataxy, but galvanism, which is of no use in this disorder, has conniderable power over diphtheritic paralysis.

"It is probable that inflammatory disease of the plantyax, such as toroidlitis, general pharyagitis, putrid sore threat, or syphilis, may give rise to more or less disturbance of the motor apparatus of this region; but it is only in diplatheria that other norre-entres suffer, so that this fact affords a means of differential diagnosis. The voice nequires a characteristic masal timbre, the modification of certain articulate sounds being very characteristic, owing to the impossibility of closing the mass-pharyageal passage. Thus voic, hoof, and ope, become vars, hear, and one."

Symptons.—Frequently the muscles of deglutition are seriously involved, and the sensibility of the faures is so affected that there is difficulty in swallowing, and fluids regargitate through the nose, or pass into the largue. The voice is weak and usual, the usual and volum are released, the power of expectoration is lost or impaired, names accommittee in the pharyne, and the taste and smell are more or less blunted. Denfaces sometimes cause. According to the experience of Dr. Maund, "the frequency of these paralytic affections is in inverse ratio to the severity of the attack of diphtheria." Out of two hondred cases attended in East Kent in 1858 and 1859, not more than ten exhibited any secondary nervous symptoms †

In other cases the eight is impaired, but the weakness of vision resulting from paralysis of the ciliary muscles passes off when the

health is restored.

Diphtheritic ephthalmia has been known to econr in connection with unliquent diphtheria of the throat and air-passages.

Occasionally there is a general loss of sensibility oming or during couralescence.

The paralytic symptoms are generally most severe on that side of the body corresponding to the threat disorder.

Paralysis of the lower limbs, and wasting of the extremities, occur in some cases. The upper extremities are rarely affected. Where the nurseless of respiration are attacked, danger is imminent. The paralysis is, however, generally carable, and yields to trestment in time.

^{*} Possess of the Thomas and Nove, by Morrell Mackenile, M.D., 1880, p. 113.

⁴ St. And Good Asso, Joseph 1969, p. 50.

Diplotheritie Opinisalaria, by Edward Naufuckip, St. Thun. Boop. Sep., vol. 4, p. 27.

The three following cases, in children of the same family, came under my notice in July and August, 1880. They illustrate many

of the precoding observations,

Case 1.—D. A.—, a female child nearly four years of age, had a severe attack of diphtheria, with copious membraneus deposit on the tensils and pharyax. There was high fever, drousiness, and albumen in the urine to the extent of openixteenth of the quantity passed. The albumen persisted for some weeks. The paralytic symptoms that followed consisted in indistinct articulation and slight squinting. Under tonic treatment the recovery was perfect.

Case 2.—II. A.—, a healthy boy, eight years of age, had membraneous exudation on both toneils and back of the pharynx. The constitutional symptoms were more severe than in the pretions case, but there was very little albumen. The paralysis consisted in double vision, equinting, articulation almost gone. Could not see black objects, but all other colors. When walking in the street, he ran up against people in passing. Two months

after this illness he was quite well.

Case 8.—A. A.—, a boy, agod fourteen, of nervous temperament, was taken ill August 8th. Diphtheritic membrane extended over the arch of the painte, back of pharynx, and left tonsil, thick, temperous, and wash-leather like. Allemen appeared on the fifth day to the extent of one-half. The two following days the urine was nearly solid, then it gradually diminished, and temperarily disappeared on September 2th. It returned from time to time, and disappeared altogether on September 20th. The paralpsis consisted in almost complete loss of sight, succeeded by double rision, imperfect articulation, choking, and occasional fainting. An ophthalmoscopic examination showed hypermetropic refraction, and thinness of choroid. On navid side, and in substance of disk, there were seen two distinct nodules of lymphlike deposit, their and well-defined; vascularity normal. The patient made a good recovery.

Hemorrhage from the thront, nose, and brouchial mucous membrane occurs occasionally in conjunction with diphtheria; also aruptions of the skin, resembling typheid fever and measles, are neutioned by different observers. Erythenes, articaria, and dark

claret spots like purpura have also been noticed.

Morbid Anatomy. On examining the bodies of children and

adults who have died of diphtheria, evidences of bronchitis and provinced are frequently seen. In the tracker and brouchial tubes the peculiar membraness formation is found, and on the removal of the exudation the nuncous membrane is seen congested and exceriated, and there are small bloody points similar to those observed in the fances. As the disease descends into the largue and tracker, the false membrane becomes thin and spends out like a transparent film, or the exudation is converted into a thick creamy fluid. The takes membrane has been observed linking the bronchial tubes to the third or fourth bifurcation. It sensitives extends to the couplings and stomach, which are found red and covered with exudation. The moreus membrane may be thekened or alcorated, and the tessils gaugemons.

The heart has been found small, and its muscular tissue pale; cases, too, of fatty degeneration have been recorded, and the parietes have been studded with black infiltrated patches and petechial spots from sanguineous extravasation. Fibrinous congula sometimes occur in the cavities of the heart, as in scarlet from and the pseumonia of children. They may be seen in the right auricle or ventricle, or in all the four chambers of the heart, of firm consistence, and so adherent to the chorde tendines, that the deposit must have happened during life.

The kidneys have been found quite healthy after death, as may be expected when the urine has been free from allumen during life; but careful microscopical examination usually reveals some change of a special character. The kidneys are sometimes only congested in simple cases, but where albumen has been a persistent symptom, some change in the intratabular structure will generally be found; the tubules may be blocked with granular matter, oily globules, blood-corpuscles, and fibrinous exudation.

The sinuses and membranes of the brain and venous system generally, have been found remarkably full of thood. In a fatal case recorded by Sir William Gull, and quoted by Dr. Greenhow, the membranes of the brain and spinal cord were in a state of suppurative inflammation.

Diagonals.—The diagnosis of diphtheria from eroup is given in

the previous chapter.

I may here quote an interesting passage from Niemeyer on the anatomical appearance of the exudation. "If the largus and traches participate in the disease, the croupous, not the diplotheritio form of inflammation of the mucous membrane occurs-that is, the surface of the mucous membrane is covered with a more or less tough and consistent falso membrane, which may readily be removed, and leaves no loss of substance after its removal. This circumstance has induced some physicians to identify primary genelae croup, which is due to catching cold, etc., with croupous largugitis canced by infection with diphtheritic contagion. I secsider this a false view. The division of diseases, according to the pathologico-anatomical changes they induce, is only a makeshift. In all cases where, as in genuine and diphtheritic croup, we find that two anatomically similar disturbances of putrition depend on very different causes, we should consider them as distinct." It is this similarity in the character of the exudation between infamoustory croup and diphtheria which has continually led observers to consider them as one and the same disease; but this certainly cannot decide the question.

The throat in malignant scarlet fever and diphtheria is very much the same in appearance, and may be confounded the one with the other. As regards the diagnosis at the beginning of lightherin, the more circumscribed redness and the peculiar vellow patrb of the exudation is, from an anatomical point of view, so characteristic, that it is conclusive orbitence of the disease. Yellowish or gravish-brown alonghs of plastic lymph on the torsils and pharynx, leaving later on a bleeding surface where the membeans is removed, are common in diphtheris; but is severe instances of either disease, asky-looking, gangrenous deposits may be son, and owing to this circumstance, a diagnosis would be imposible. In scarlation, the constitutional symptoms preceding the throat affection are more marked, the skin is pungent and bot, and the temperature is high; whereas in diphtheria, the throat may be severely affected in the absence of these symptoms, and the pulse and respiration are low. In both diseases the lymplatic gineds are involved. The throat generally presents a more uniform redness, and the tougue is characteristic in searlet fever. The soft palate and tonsils have a milky or oreamlike aspect; there is a thick layer, which soon clears off, leaving the parts beneath augry and red. In diphtheria the exudation is more deeply seated,

^{*} Nacostyer's Practical Medicine, vol. it, p. 61.k.

and it comes off in dense membranous layers, representing a cast of the surface on which they have formed.

At a very early stage it is not easy to distinguish the redess of dipletheria from the inflamed sore throat of inflamentory entarts, in which the tonsils are tunid, and have a thin layer of lymph upon them. The pharyux is vascular and irritable, and the lymphatic glands are tonder and enlarged; but they go down when the cold is relieved. In healthy subjects, however, an inflamed state of the corvinal glands is exceptional in cases of tondilitis. I have many times known children with a temperature of 10%, or more, in this complaint, and the throat so swollen and the fances narrowed, that the smallowing of liquids was most painful, and yet the glands in the neck were not enlarged. When they are swellen there is fear of a strumous taint, and the specific inflammation is often sufficient to excite chronic enlargement, if not supporation. Then there is a discharge from the nose, and the fever is considerable, with thirst and difficulty in swallowing.

The diagnosis from tonsillitis can generally be made; in the latter affection the constitutional symptoms are not of the low and adynamic type which belong to diphtherin, and one tonsil is men affected than the other.

Scarles fover and dightheria have prevailed together at the same time and place, and each disease has exhibited the characteristic local symptoms. One member of a family has had the peculiar existation of the fancer, but no rash or desquaration which scens in scarlet fever, "Sometimes," says Dr. Gesenhow," "cases of dipletheria and searlet fever have even been intermingled in the same family, or dightheria has appeared in persons who have been in communication with patients suffering from searlot fever." Another difference between the two discuses is, that the albumnurla of scarlet fever comes on at a late stage, often at the col of a week or mouth, after the cruption has left, during the period of desquamation, and it goes on to dropsy and amsarm with hemsturia. In diphtheria, albuminuria is an earlier symptom when it does occur; hematuria is rare, and dropsy does not result, nor is the excretion of urea lessened. The arine does not present the smoky appearance which is common in scarlet fever, but casts of the prinary tubules are generally found. The presence of albumen in the urine is by no means a constant symptom even in

^{*} On Diplatteria, p. 202.

severe cases, but when it is present in large quantity it is a serious indication. Amusarca is rarely present except in cases complicated with searlet fever. Urasmia has not been observed in connection with the albuminum of diphtheria; but excess of phosphates and unites, with high specific gravity of the urine, is of common excurrence.

It has been asked whether there is any relationship between digatheria and enteric fever, and it appears certain that the two diseases are not unfrequently associated. Dr. Murchison considers that it is not true diphthoria, the threat complication in enterio fever being frequently found where there is no dightheria. As the conses of the two diseases are much alike, we should expect them to prevail together, and not look upon their existence as a mere coincidence. Dr. Greenfield brought before the Pathological Society (November 6th, 1877), a specimen of diphtheritic membrane from the laryox and pharenx of a child, aged five, who had been under the care of Dr. Murchison at St. Thomas's Hospital, suffering from unmistalcable enteric fever. There was ulceration of Porer's patelies, and also swelling and round excavated sloughing nions in the lower part of the ilenm. In addition there was becorhopmenmonia; but no false membrane could be seen on the fames or the tonsils, which were red and swollen.

As to the communicability of the disease, it is hold to take place through the secretions of the throat by Bretonness and others; but the experience of many medical men during the epidemic of 1838 and 1859, does not concur in the opinion that the disease is communicated in this way. In contemplating the record of cases, lowever, we can hardly fail to observe that the diphtheritic secretions have induced ophthalmia and throat affections in those persons who have been nursing the sick, or have seized upon the modical attendants who have been close enough to receive particles of the explation when the patients have coughed or special during an examination of the throat and fances, or the application of some local agent. The character of the disease so induced, has been in a few instances that have come within my knowledge, so precisely like the diphtheritic exudation, that I think the evidence of prepagation by contact with the secretice, cannot be set aside. The disease has spread with rapidity in the cottages of the poor, where the appliances of the sick are scanty, and desaliness is disregarded. Then, again, a child laboring under dipletheria has been brought from a distance to its own hows, and soon afterwards the discuse has attacked other members of the family, when precious to its return, not a single case had happened in the house, or the surrounding district for many miles. Dr. Squire notices that the more abundant the secretion in particular cases of dipletheria the greater the danger of infection."

I think we shall be forced to admit that dipletheria, like typhoid fever, has semetimes a spontaneous origin, when soil and sense, temperature, fifth, and uncleanliness condine to lower the general health and contaminate the blood. If it were not so, how shall we explain the alarming outbreaks of these diseases in school and bolated homes, and their tendency to remain within a limited

area, and not to spread in an epidemic form ?

The infection of the atmosphere by the exhaled air of the sick patient, leaves no room for doubt that this is another mode by which the disease is propagated. Children who have been in the same house with diphtheritic patients have contracted the disease, when they have not ventured near the sufferer; and there are no doubt other vehicles for the transmission of the poison, subtle, tenerious, mysterious, ever ready to seize upon the young. "The greater frequency of the disease among children than adults does not seen to be due to greater predisposition of the former, but to their being more exposed to infection than adults are."

Decision.—This is a disease demanding local and constitutional measures, and from the first neither should be disregarded. Sometimes the local should be the most energetic, and sometimes the constitutional; but from the commencement the treatment must be supporting, if not stimulating, and these measures that are most to be relied on in exhaustion and syncope are to be held in close reserve. Like other epidemics, the disease does not admit of depletory measures, and all practitioners who have had a large experience of it insist upon the necessity of employing a supports ing plan of treatment. Each case will require some modification in accordance with its poculiarities and tendencies, so that it is not easy to lay down any exact rules to follow. The patient should be placed in a large and well-ventilated room, the temperature of which should range from 60° to 65°. He should be

Boynekhi's System of Medicare, vol. i, 2d edit., p. 115.

Niemerer, op. cit., vol. li, p. 615.

kept absolutely quiet in bed, with the head low, and all excitement carefully goarded against.

At the commencement of the disease, a purge of calomel and rhularb is sometimes required, so that some of the poison may be eliminated by the intestinal canal. This has been insicted upon he Sir William Jenner; and other observers have advocated this treatment at the beginning of the disorder, when the strength is cond to it. Under most circumstances, a mild saline aperient, to keep the bowels regular, will be occasionally required, or a small dose of easter oil; still, caution must be observed in the administration of apericuts. Our best guide in this matter is the mildness or severity of the attack, for in the malignant form the child is overpowered by the poison at once, and the pulse is so feeble that any depressing remedy would only hasten the rendercy to fatal rencope. Milk in large quantities, best ten, chicken broth, and eggs are the forms of nourishment best suited to malutain the flagging strength. Wine or brandy will be almost invariable needed, and the quantity must be regulated by the strongth and frequency of the pulse. Where there is a tendency to syncope or failure of the heart's action, or the pulse is slow, very frequent, or irregular, considerable quantities of alcohol can be taken with alvantage. Perseverance in the administration of food and medicine is imperatively demanded, and the attempt must not be abandoned under the impression that the child is unable to swallow, for this is constantly found to be erroneous.

When exhaustion is the leading feature of the rase, the child should not be allowed to skeep too long without neurislment. If the throat is pointful, and there is thirst, a piece of ice to suck is very grateful and refreshing. A small quantity of ired water should be offered frequently if the mouth and lips get dry quickly. In the shape of medicine, the curbonate of ammount, with the timeture of bark (Form. 11), is an excellent combination for supporting the system against exhaustion. When the skin is hot and the temperature high, ice, cooling drinks, and displacetics.

will be useful; with these may be combined the fincture of the perchloride of iron," or the iron may be given alone or with olde rate of potash. In most of the hillaminatory throat affectious of chibiren, this proparation of iron has a womlerful effect, and is as specific as in crystpelus, which may be possibly due to some antiseptic properties which it exerts locally, and possesses after its entrance into the blood. It requires to be given frequently, and, according to some authorities, in large doses. A small dose (my to mx), with or without the dilute hydrochloric acid, once in four hours. is often enough in mild cases. If the tougue is furred and the breath fetid, chilerate of potash, in combination with the acid, is an excellent remedy, and recovery will take place under its steads continuance. Quinine, salierlic acid, Isomoute of sods, when the temperature is high and the system depressed by the septic nature of the disease, are all useful. When the throat exhibits dark and softened portions of explation, with a tendency to bleed when touched, or there is been orrhage from the amoons surfaces, then the perchloride of iron must be combined with it; and in this formidable complication, a full dose should be given every hour or two, till the urgent symptoms are relieved. In most cases I prefer a mixture consisting of iron, chlorate of potash, and bydrachloric acid. † It is particularly suitable when the exudation is firm, the tongue coated, and the threat exhibits no hemorrhagic tendency.

The chlorine drink recommended in scarlet lever is equally of service here. It is grateful to the little patients by relieving the throat and febrile symptoms when they are present. It also possesses antiseptic properties, and improves the character of the exudation.

Quinino and the mineral acids are also useful variously con-

Must. External applications to the throat, in the shape of leeches, blisters, and counter-irritants, are in no case requisite, and will do burn. Warm poultices, fomentations, or water-dressing, are comfortable and useful.

The applications to the threat internally, are those indicated in warlet fever, and the same precautions as to strength are to be observed. In young children who cannot gargle, a solution of borax may be applied to the throat (5ss, to the 50), or equal parts of the liquor ferri perchloridi and honey may be used with advantage. This is perhaps the best astringent application. In a case that came under my cure a few years ago, a thick solution of Monte of pointh, borax, glyceria, ami honey," gave much relief to the throat. At an early stage, when the membrane is thin on the fances and tonells, a solution of nitrate of silver (gr. x or gr. xx to the Zil, applied with a camel-hair brush, twice in the twentyfour hours, has been of benefit. The application of the solid nitrate of silver must be cautiously resorted to; indeed, it is questionable whether this or any other caustic, as hydrochloric soid, or the acid nitrate of mercury, in ever mecessary. They increase the pain and difficulty of swallowing, and at the same time aggravate the local ulschief. If there is fetor of the breath, and the parts incline to he sloughing and gangesnous, the solution of chlorimited soda, in the proportion of one drachm of the solution to two ounces of water, is an excellent application. This, and the iron solution, are two most valuable measures, according to my experience, in every stage of diplotheritie sore throat. Some children are so alarmed and frightened at the attempt to press down the tongue, and applyapplications to the throat, that these measures had better be given up altogether in such cases. Nervous and delicate children are almost thrown into convulsions by their straggles and resistance, and where these applications cannot be used there is consolation in remembering that escharotics are of doubtful efficacy, and even, according to some English and foreign physicians, who have had great experience of the malady, decidedly injurious. In diph-

^{*} Formin 55:

theritic affections of the throat, the carbolic arid spray will often be found very useful, just as it is in the faucial affections of scatlet fever and measles. Lime-water, sulphurous acid, lactic arid, etc., have been also used in like manner with success. The most covenient plan of using the spray is to employ Siegle's apparatus, or the hand spray of Dr. Andrew Clark.

As regards the operation of tracheotomy when death threatens from sufficiation and dyspaces, Professor George Buchman, of Glasgow, has recorded some interesting cases of success. Out of thirty cases he had cleven recoveries.* He has subsequently informed me that in every eight tracheotomics performed on children practically morihand from sufficiative membranous officion into the traches, he has saved three children, and this is true of over fifty cases operated upon.

Two interesting cases of successful tracheotomy, in the last stage of diphtheria, were brought before the Clinical Society by Mr. George Lawson and Mr. Pugin Thornton (Feb. 28th, 1879). Two cases of diphtheritic laryngitis have been recorded in which recovery also followed tracheotomy. The first case was that of a boy, six years of ago, who was admitted into the Middlesex Hospital, under the care of Dr Coupland, May 30th, 1880. The see cossful issue was owing to the operation having been performed at an early period of the disease before much false membrase hal formed. The second case was also that of a boy, seven years of age, who was admitted into the Children's Hospital, under the care of Dr. Gee, on Sept. 15th, 1879. Recovery followed quickly, notwithstanding the extreme dyspines at the time of operation, and the large quantity of membranous casts expelled through the tube afterwards. The following case had a different termination, owing, as I believe, to the delicate health of the child, the delay of the operation, and the collection of mas and false membrans in the traches. On June 18th, 1880, a female child, three years of age, was admitted under my care into the Samaritan Hospital

Brit Med Josep, 187A, vol. 11, p. 283.

I A standard table of all the cases, with remarks on the auchtion demanding tracket may, will be found in the British Medical Journal, not. it, p. 505, 1881. "Taking the whole of the cases, the result is that nearly too out of every fix approxima were recentled; and as the operation was more performed unless these was to hope of moreovy otherwise, it may be fairly stated that the lines of these minimal children were sent by irreducions."

² The Laucet, 1880, erd, 5, p. 500.

with diplotheria, symptoms of commencing laryngeal obstruction, and great prostration of the strength. The face was pale and the certical veins normal, but the respiration was a hearing and noisy, and the cough frequent and laryngeal. Air entered the lungs, At 4 p.m the child was not so well, the head was thrown back against the spine, the respiration was more embarrassed, and the spignstrium was retracted at each inspiration. Tracheotomy was performed at my anggestion by Mr Knowsley Thornton, the patient being under the influence of bichloride of methylene. As sees as the tracken was opened, a tenspoonful of purulent matter escaped, and the shild shortly after expired from shock and asphyxia. A post-mortem examination rerealed the upper surface of the soft palate and uvala uniformly covered with diphtheritie patches. Another ratch fined the mucous membrane of the larynx inmediately below the right yourl cord and projected into the glottis; a long slough lined the mucous membrane of the traches, below the incision, extending almost to the division of the brought. The larynx and trackes were filled with purnlent finid. Both lungs were slightly congested, but floated in unter; the brouchi contained some purplent fluid, but no false membrane. There was a large decolorized sizy clot in the right nuricle; no abnormal argentances in the liver, mucous membrane of asopliagus, stomash, or intestines. The mesenteric glands were much enlarged, but not softened.

A case of diphtheria in a child is recorded by the late Dr. Murclists, in which tracheotomy was performed on account of the argent dyspaces. The points of most interest lay in the morbid changes found in the intestines. After the operation a little thick explation was removed, with relief to the locathing. Death occurred in twenty-five hours afterwards. With the return of the enforcesed breathing the temperature rose to 107.6°, and at the time of death it fell to 194,5%. The interior of the larynx and traches was completely lined by a layer of false membrane, which was firm in some places and easily detached in others. At about the fourth ring of the tracken it could be separated in a complete layer, beneath which the surface was red and raw-looking, and "studded with minute vascular points." The larger broachi, as far as the third or fourth division, were filled with a cordy fluid, and some of the smaller brought were dilated. The state of the small intestises was the chief point of interest in the case, as the child was said to have been quite well the day previous to admission. The solitary and follocular glands of the small intestines were distinct and prominent throughout, and there were three or four small rounded aleers apparently connected with them at the middie third of the ileum. In the ileum, also, there were three or four abors of irregular shape with raised odges, and the Perer's natches had undergone a change resembling that met with in the surfer stages of typhoid fever. The large intestines were healthy. Beth lungs were collapsed and dense; the right cavities of the heart were distended with dark, perfectly congulated blood. It would appear that although trachestomy temporarily relieved the distreasing dyspaces, no hope of recovery could have been entertained where the local mischief was so extensive and the effect of bloodpoisoning had become so general."

But supposing the non-identity of croup and diphtheria is almitted, and that the diseases are in many respects clinically and practically different, still both are prone to terminate fatally by exhaustion, or by sufficiation; and these urgent symptoms would seem, at least, to domand the same line of treatment. When the latter condition threatens, and all other remedies have proved meless, we allow that tracheotomy is justifiable, and that the operation has rescued many a little sufferer from an ageniring death. Henceforth we must look upon trachestomy in diphtherin as a peoper step to take when the child is beginning to struggle for its breath, and the strongth is departing; when the features are livid from obstruction to the circulation, and the mischlef is limited to the trackes and larynx. If the larger bronchial tubes are involved there will be no objection to the operation; but if viscid secretion is blocking up the smaller tubes, and there is any sign of pneumonic sonsolidation, then the operation had better nor be attempted.

For the angenia and nervous affections which follow diphtheris, citrate of iron and quinine, the mineral acids and columba (Form. 14-20, should be employed. Strychnia and galvanism are also very useful in diphtheritic paralysis. For any albuminuria and prolonged weakness, the tincture of the perchieride of iron and hydrochloric acid are the best remedies. Change to the senside is important in protracted cases.

Parti-Sons: Ferrorably in militation where the habit is post of Categorium. Describe of polymons—Quarter both—Proprietion of trans—Chitaire all—Marshim is stall and posted limits.

This affection is recognized by a peculiar crowing noise which takes place during inspiration. It is so characteristic that when once heard it cannot be forgetten. It arises from spasmodic narrowing, or temperary closure of the glottis and laryax. It is a form of internal convulsion—a clouic spasm of some of the respiratory unsecles. As a rule, the general health is below a right standard, and the child is restless and out of sorts before the seizuro happens. The disease is frequently associated with general debility, strophy, or convulsions.

It is not uncommon for slight wheezing and catarrh to procede the development of the symptoms for some days, but it is not parally attended by cough.

Males are more subject to the disease than females. "Out of my fifteen cases, eleven were boys, so that it comes as if the largue of trade-children begins, even in the very earliest youth, to distinguish itself in form, or at least in physiological activity, from that of female children."

Symptoses.—When a child is seized with a sovere attack he struggles violently, and fights with his hands cleached, as if about to suffer instant sufficiation; the face is livid and congested, the eyes are staring and sufficed, the servical veins are distended, the head is thrown back against the spine, and the whole body is in tremulous agitation. After about a minute or two, and some ineffectual

efforts to breathe, the spasm becomes relaxed, and air passes down the laryax with a shrill crowing sound, on indication that all inmediate danger has departed. The child now cries and books terrified, and then generally falls askers. In exceptional costs, the faces and orine may be passed involuntarily, but I believe this to be rure.

During the seizure, when the muscular struggling is at its height, the thumbs may be noticed tightly bent into the palms of the hands, and the toes turned inwards and towards the soles of the feet. The wrists and ankles are similarly flexed inwards.

It should be remembered that all cases are not equally severe, nor equally frequent. Some are milder than others, the intervals are longer, and the spasms less pronounced; the child has a mild attack of catching in the breath, with slight and occasional crossing at long intervals, and then perhaps these symptoms pass off altogether if the general health improve; but if not, the spasms may gradually increase in frequency, and several attacks occur during the day. The spasms, which begin slightly in the largu-gual souscles, may become more and more severe, and in some instances terminate in general convulsions and death. Under any circumstances, the seizures leave the child exhausted and descay, especially if they are frequent. The attacks often some on in the night, or when the child wakes out of sleep, or attempts to take food or drink.

When the bowels are disordered, or there are worms in the intentinal canal, some children are liable to a local, ringing cough, of a purely nervous character, which alarms parents. With it there is excited pulse and flushed face, but all these symptoms disappear when an active aperient is given, and the source of irritation is removed.

The duration of the disorder is uncertain. In some instances it occurs more or less during dentition, and ceases when the teeth have appeared; in other instances it slowly or suddenly grows worse, and ends in convulsions or asphyxia. If the disorder teen from time to time it is soldom fatal. Spasm of the glottis has been often assigned as a cause of sudden death among infants and young children, which could not be otherwise explained. Dr. Churchill says, "I confess that I am inclined to believe that many of the deaths attributed to the nurse or mother overlaying the child are, in truth, cases of sudden death from spasm of the

Courses.-These are predisposing and exciting. Among the former are infancy and the stramous diathesis; among the latter teething and worms in the intestinal canal. Enlargement of the brorelital and mediastical glands has been also summerated as a cause of the affection, by pressing on the inferior recurrent larvagoal nerve. "Laryngismus has been attributed to colargement of the thymus, but this view is not now susertained, one very good reason being that post-mortem examinations show that in many instances there is no enlargement of the organ. Moreover, in cases where a large thymns has been found, there has been no laryngismus." Further than this, the disease is rare in young infants where the thymus gland is largest. "M. Herard examined the thymns gland in six children who died of internal convulsions, and in sixty who died of other affections, and was not able to discover in its condition any causative relation to this disease. Indeal, cases have been reported in which the thymns had undergone more than its usual atrophy at the time when the convulsion occurred (Hasse).": Though enlargement of the lymphatic glands in the thorax is constantly present without causing the disease, I easnot avoid the conclusion that there is some connection between the peculiar shell squeaking cough when the bronchial glands are salarged, and laryngismus stridnius. The discuse is more frequent in damp and in moist situations than where the air is pure and dry. It is far oftener observed in towns than in healthy country districts. It is also said to be sometimes hereditary, occurring among families of nervous excitable persons. I have myself known three children of the same family who were affected with spasm of the glottis. "There are families in which all the children suffer more or less from it, and Powell even relates an instance where, out of thirteen children, brought up by the same parents, only one escaped the disease."5

As to the period of life when the disease is most common, we may mention that of infancy, and about the seventh mouth when there is disturbance in dentition. After the age of three years it

^{*} Dispass of Children, 1848, p. 331.

[†] Haynold's System of Medicine, vol. ii, p. 200.

I Essenses of Children, by J. Lewis Smith, M.D., 1869, p. 194.

Vogel on Disasses of Children, 1874, p. 274.

is much less frequent. "In 31 out of 87 cases, of which I have preserved a record, the symptoms manifested themselves between the ages of six months and two years, or just at that time when the process of doubtion is going on with the greatest solivity," "Of 226 cases which have occue under my own notice, 174 were in the first year of life, and the roundining 52 between the second and third years; and the relative proportion of the sexes was 150 boys to 76 girls. In both parents and children there was very frequent evidence of rickets." In every case of burgaginess straints (save two) which has some within the experience of Sir W. Jonse, the child was the subject of rickets."

Most observers agree that laryngismus stridulus is not uncommon in cases of thronic hydrocephalus, and this has been pointed out by West, Ebsisser, Vogel, and many others. Where the nervous system is excited or exhausted it is sometimes seen. I have known attacks to occur so often as to continue me that this is by no means an uncommon cause. Fright, alarm, emotion, anger, loud noises, etc., are all to be enumerated as excitants of the seconts.

The researches of Dr. Marshall Hall claborately explain here the disease may originate through irritation of some of the custial and spiral nerves. "Spaces of the glottic is an excitation of the true spiral or excito-motory system. It originates in

- "A. The triberial cores, in teething.
 - B. The purposepostric, in over or improperly fed infants.
 - The spinal zeroes, in constitution, intestinal disorder, or eathersia.

These set through the medium of

- 2. The spinist moreous, and
- a. The infirm or resurrent furginged, the constrictor of the larynx.
 - The interestals and disphragmatic, the motors of requiretion."

When the disease is once established, a violent fit of crying, or any attempts at swallowing, or endden movements will being it on. Changing the nurse or giving improper food will invite an attack in a delicate child, especially if it is the subject of convulsions, between which and laryngismus there seems to be a close

[&]quot; West on Discount of Infrary and Childhood, 1850, p. 185.

I Repelde's System of Medianic, vol. 1, 54 edit, p. 873.

connection." The following is a fatal case in point: On the 27th of January, 1875, I was requested to see the mule child of a lady residing in a large and well arranged home in the west end of London. He was five months old, and was born strong and healthy. A wetnurse was procured for the first three mouths, when she left, so her milk was supposed to disagree. The child was fed with milk and Robb's biscuits, and for a few days before my visit, "Chapman's wheat floor" was substituted, which appeared to agree. The child had been successfully vaccinated on the 25th of December from a healthy infant, and from this time the mother thought it had become pullid and flabby. The general condition seemed, however, satisfactory, and the pullor was probably due to his being shut up in the house. There was a large family of shildren, but pone of the others had ever suffered from a similar affection or from any illness of importance. On the day previous to my visit the child was seized with what the nurse termed group, being mable to get his breath for some moments, the attack roding in a crowing inspiration and a wheezing cough. The child was irritable and restless, and could not obtain sloop; the bowels were singgish, and the motions dark and offensive. I prescribed a pomber consisting of locarbonate of solu and rhubarb every night, and a mixture of bromide of potantium and sal volatile three times a day. The shild to be fed on cow's milk only.

January 28th, 9 s.s.—I received a note to say that the child had had four convulsions since my last visit. The nurse had carried him in her arms all the night, and if she attempted to put him down he could not breathe. The mixures were marked by fixed syes, pallor of chesks, darkness of the lips, and a convulsive movement of the body. Some of these attacks ended in a long trawing inspiration. When I approached the child at my visit he seemed almost electrified, starting in the nurse's lap, and looking dreadfully alarmed. There was some coryga, with running of the tose and eyes; the skin was moist and warm; temperature 100°, pulse 156; respirations 36, noiseless. At 3.30 a.s. the bowels had

^{* &}quot;Out of 50 mass of Intensions, of which I have mass, 19 had had relampted for "-De time, St. Barthelomes's Hospital Reports, vol. iii.

[&]quot;The communic of general convolutions in pronoccion with larguigness, indicate that its morbid action extends to and territors more larger group of nerve-coils than in the local amount, probably cities the whole of the modulis chloragets, or the corporal profragmation also,"—(in Proceed Novem Districts, 2, C. Handfeld Joses, M.E., 1976, p. 63).

acted well, the motion being of a light rellowish ochrey color, with slimy discharge. The fixed ordered to consist exclusively of two parts of sow's milk and one of sweetened barley-water. In the shape of medicine, a mixture consisting of citrate of potash, broadde of potassium, and timeture of healume.

12 st.—Sleeping tranquitly, but on being touched he started convulsively; there had been one attack of drowing since my had which. At 5 r.m. he was sleeping, and there had been no return of the crowing; at 9 r.m. he was resting in his mother's lap; the face arm calm and peaceful; the skin cool; pulse 120.

2)th, 9 a.s.—The bowels had acted moderately three times, but the child was continually drawing up his legs and crying, as though in pain; there had been no sickness and no convulsion. He was rather pale; pulse 120, respirations 32; the skin was cool, and the breathing, as ascertained by patting the ear to the back of the lungs, was unembarrassed; the pupils were normal, and be looked round intelligently. I considered be was likely to recover. I went downstairs, and just as I had reached the hall I was summored again, when the mother handed me the child, whose lips and face were now dark, his limbs relaxed, and he had ceased to breathe. Death must have taken place in a minute from asphyxin.

Cases are sometimes to be met with of a more chronic character, and where there is no immediate danger to life.

Case 2 .- On April 12th, 1875, a female child, fifteen months old, came under my care at the Samaritan Hospital, which had suffered more or less from laryngismus ever since she was six months old. The child was rickety, with the atrumous diathesis strongly marked, the head was large, and the anterior fontancio wide and prominent; the veins were discended over the scalp; the face was pule and flabby, and there were only six teeth. Three months before I saw the child she had had convulsions, which continued more or less for some time. The child was often breathloss, the respiration habitually accelerated, and the cough croups. If excited in any way, as playing with other children, the attack was certain to occur, and so lad was it that her mother throught she would sometimes die in it, as her face become dark and purple. Sudden changes of weather, as from heat to cold, or the reverse, were certain to invite a seizure. It sometimes came on in the night. The mother stated that she had suckled the child,

having had plenty of milk, but her health was delicate; and till within a short period she had scarcely ever given her any other form of nourishment. The shild made a fair recovery, but remined delicate when I saw her a year after first coming under treatment.

Death may take place [1] from asphyxia, as in the first case related, where the envitles of the heart are full of blood, and the large engaged; (2) from corebral congestion and serous effusion; (5) from exhaustion and failure of the vital powers. "The suides death, which is by no means uncommon in this disease, depends, I conseive, on the transmission of irritation along the cardiac fibres of the vagi to the heart, which is then arrested in its action, just as when the passumognetries are strongly galvanized.""

Pethology.—The disease appears to depend primarily on irritation of the pneumogastric nerves, which is provoked by disease of the cervical or bronchial glands, or by irritation of the fifth serve, as from teething, or by disorder of the stemach and intestines.

The irritation is propagated to the inferior or recurrent largugral nerve, and the muscles of the larynx are thrown into spesm. The largue is entirely free from inflammation, and there is no lecton of its mucous menderane. It is a purely neurosal affection, and whatever anatomical changes may be found after death are in most cases consequences, rather than causes, of the scizare. "It some rather to be an independent affection of the par vagum, or of its recurrent branch, due either to pressure along some part of the course of one of these nerves, or to centric irritation at the root of the vague; or else we may be compelled to regard its stalted sensibility as a reflex phenomenon arising from excitament of some other nervous trunk. In most cases the pathogeny of this discuss is obscure." + Dr. West likens the discuse to laysterical fits in the female, and says that both affections are most common when the processes of life are most netive." In some cases, offusion into the ventricles, congestion of the brain, or even fumors in the cerebral substance, have been found after death.

[&]quot; Hardfield Joses, M.R. ep. cit., p. 655.

[†] Niemeyer's Practical Moderine, 1875, vol. 5, p. 51.

f Op. sal., p. 181.

Tubercle of the lung and bronchial congustion have been also noticed. Still meelid appearances are sometimes entirely absent.

The diagnosis from cross is given in the chapter under that loading (page 329), but it may be here stated that in largugianess the suddenness of the science and its departure, the normal breathing in the intervals of the actacks, and the obsence of fover and inflammation, are the distinguishing features of this peculiar complaint. As the disease increases there is a disposition to general convulsions, whilst these occur only in the last stage of cross-The crossing sound is not unlike that of whooping-cough, but in largugismus there is no expectoration, nor comiting, nor catarrh in the strict sense of the term.

The proposes may be considered generally favorable in slight ences, when the sciences are not frequent, the health tolerally good, and there is no complication. When the case is mild, and the crowing comes on at long intervals, it usually yields to judicious treatment. Still, the discuse is always to be regarded with anxiety, and especially, if severe, from the liability to cerebral complications, convulsions, or sudden death. "Out of lifteen cases of which I have kept a record, eight died. Billiet and Barthez, out of nine cases, and Herard out of seven, observed in each only one single instance of recovery."

Touthand,-The first indications are to remove all exciting causes. If the bowds are disordered they should be set right as soon as possible by proper aperients, and healthy digestion promoted. If the child has taken a heavy meal, or indigestible field, an emetic may be advisable; and should the gums be swellen and dentition appear to invite the complaint, they ought to be scarified. The child should occury an airy apartment, and poise and excitement be precluded. If someduring the paroxyam it should be kept in an upright position, and the windows opened, so that it may be encouraged to broathe. In scrope cases, especially if a course sicu threaton, it may be immersed in a warm bath, whilst cod water is sprinkled at the same time over the face. Dr. Morley Rooke recorded a case of laryngismus stridulus in a child nine months old, where occlusion of the largux during the fit produced symptoms like those of a "recently drowned person." The little patient "showed no signs of life" when first seen in the selente; the lips were blue and swollen, the face a livid gray, and the eyes

half closed and glassy. Dr. Rooke thrust his finger between the tooth to the faures, when the child gave a short heave and a grap; on repeating the movement inspiration took place, and in a few more seconds breathing ensued. On two more occasions, when orclasion of the larynx was equally severe, a similar manouvre brought round the child. This is a mode of treatment well worth bearing in mind when the child threatens to die from spasm of the glottis. The cure our completed by brondile of petassium, which was taken for eleven months." Dr. Wardell also points out the beneficial effect of "rotating the finger in the threat" in these cases; it induces an attempt to vemit, when the larrageal muscles become relaxed, and air is admitted into the tracken. He says it is the first thing to be done, and he has even it succeed when death seemed imminent,?

In extreme cases, where death threatens from asphyxia, the operation of tracheotomy should be employed. The inhabition of eldoroform has been recommended in some cases, but then its influence soon passes off, and it cannot be said to have any carative effect. When there is much restlessness, and the child can obtain no sleep, the excitability of the nervous centres must be raimed, and for this purpose small doses of morphia may be canticusly employed. In the intervals of the seizures the borrels must be kept freely open, so as to remove all sources of irritation that might sympathetically excite spasm.

Among the chief drags are belladonen, in the form of extract te tincture, which sometimes has the effect of diminishing the giottle spasm, but in many cases it fails altogether. Bromide of potassium is very serviceable, given with citrate of potash, salvolatile, or quinine, according to the peculiarities of each case ! Carbonate of ammonia, benhane, bark, and mild preparations of iron, as the ammonio-citrate, or the syrup of the iodide are remedies to be selected. If the child is strumous and rickety, or in my way delicate, rod-liver oil is invaluable.

² Female 56:

R. Potes, beautil, Tired quinter, a diffreering. Asperts of

A temporatid three times a day. For a child one year old,

Diet is of great importance, and, when carefully selected, the disease may disappear without drugs. If the child is fed at the breast it is sometimes advisable to change the nurse, or to give cows' or asses' milk. If older, the food must be light and autritions, and given frequently in small quantities. The clothing should be warm, and if the child is not too ill be ought to be taken out in the open air daily. Sponging the child's chest with cold water may be practiced with advantage.

CHAPTER XXXII.

PERTUSON OR WHOOPING-COUGH,

Whoorest-count is an infections disease of early life, varying in duration from a few weeks to many months. It is characterized by a pseuliar parexyamal cough, and irritation or inflammation in the linking membrane of the air-passages. Sometimes whospingcough prevails as an epidemic, and sporadic cases are common at all periods of the year; sometimes the attacks are mild, and sometimes they are highly dangerous to life. It may attack very young infants; but children between the ages of one and seven are nost liable to it. The mertality appears to be greater among females than makes. It may be complicated with pulmonary or combine disease, or it may run its course from beginning to end with much spasmodic cough and scarcely any bronchial affection. In two or three instances I have met with the disease occurring a second time, and such is also the experience of other observers. A lady, whom I have seen professionally for many years, assures me that she lad whooping-rough when a chibl, and a second and very telions attack when over forty years of ago. The late Sir John Forbes had an attack of whooping-cough about a year before his death. Dr. Easton, of Norfolk Crescent, has kindly furnished me with the details of two very remarkable cases that came under his care. The first case was that of a gentleman in his sevente-first year, who resided in the West-end of London. On April 14th, 1869, Dr. Easton was consulted. He ascertained that the putient had had a cough for a week, which resisted the usual domestic remedirs. The cough increased in frequency and severity, and on the 18th he first whooped distinctly. On the 11th of May he was well enough to leave town. During the attendance he had shown unmistakable symptoms of whooping-cough, the paroxysms occurring very frequently, and being often followed by vomiting. On April 24th, whilst in attendance on this patient, Dr. Easton was summoned to see Mrs. P-, in her 94th year, the mother of the above. She had been in the habit of receiving daily visits from her son, from whom she no doubt had raught the disease. She had a spasmedic cough, which gradually increased, and in a few days she had also well-marked symptoms of pertussis. The cough continued until the 24th of May. These patients had not previously suffered from the discuss to their knowledge.

As to the nature and origin of the disease, a wide difference of opinion provalls. In the earlier stages of simple and uncomplicated cases, nervous irritation holds a very prominent position in the chain of causation, and this appears to be the opinion of most writers. Some have ascribed the source of mischief to the stomoch, others to the lungs, and others, again, to the phrenic and pre-unogustric nerves. Dr. Copland attributed the sent of irritation to the modulla oblongata and base of the brain, whilst by some, the nervous system generally has been considered at fault. That in many cases the pneumogastric nerves are the sent of great irritation, and that the brain is involved through the medium of the sympathetic, is certain; but whether they are primarily or assontially concerned in the production of the psculiar phenomena appears to me doubtful. Whooping-rough depends on a materies model in the blood, having a special affinity for the largest and

organs of requiration." It has a tendency to throw the misrles of the glottis into violent spasm, through irritation of the inferior laryngeal nerves, which not only prevents the expulsion of the mucus no largely secreted by the windpipe in this affection, but by the violence of the coughing, and the extension of the irritation to the main trunk of the pneumogastrie, affects the atomach and causes vomiting.

The latest or incubation period may last from one to three weeks. Dr. Squire estimates it alout a week, and Dr. Bristowe about a fortaight.

The disease may be said to have three stages :

- 1. The cotarrhal.
- 2. The spannishe
- 3. The learning to last stage,
- 1. The control of stope is usually ushowed in with most of the symptoms of a common cold, such as language and febrile disturbance; but it should be horse in using that the spasmodic stage may tometimes precede it, and the whose he heard before any bronchial irritation can be detected. The obild is prevish and restices at night, the nose furnishes a slight discharge, and sneering and tickling cough soon sneeced. It is the severe and paraxysmal character of the cough during this period, with a penistent restless and feverish state, that auggest—in the absence of genuine bronchitis symptoms—the approach of pertussis. The cough for some days may be hard, frequent, and irritating; but there is neither distinct whoop nor expectoration. Until the whoop scens we are in ignorance as to the unture of the disease; while even if we were not in ignorance, we should still be without any specific to out it short or ward it off.
- The specimelie or characteristic stope is recognized by an increase in the frequency and severity of the cough, and a change in its character. The fit of coughing is painfully prolonged and spasmodic; the little sufferer opens his mouth wide, as though he

The Reparter Orneral includes whooping cough among the principal dissues of the symmic class. Like small-poor, menales, and dightherin, scarlet fever, and typhold force, in prevalence is sometimes great and fact. Thus, of 1922 deaths regimend in London for the week emittee May 200, 1875, 2 died from small-poor, 23 from master, 31 from societ fever, 16 from dightherin, 11 from whooping-cough, 25 from different factor of fever, and 15 from disorders, so that of those 201 deaths from synaple flower nearly half arose from final cases of whooping-cough.

were choked; there is an attack of romiting with it, and the escape of some phlegm and muchs from the air-passages. Before the science comes on, the child seems as if he were inwardly struggling to suppress it, and he has a very nuxious aspect. When the cough ours really begins, the eyes are smolled and bloodshot," and tears run down the cheeks; the lips are bluish, and the fam-has a pullid. bleated look; the veins of the forehead and neck are distended. owing to temporary arrest of the circulation through the lungs, the pulse and respiration are much increased in frequency. When the cough is very severe the child may bleed from the mouth and nose, owing to the turgid and congested state of the mucous memleans. In consequence of the extreme distension of the capillary Mondressels, they rupture. Hamorriage, indeed, from the month during the congestive stage, when the cough is severe and prolarged, is extremely common, and will recur for weeks together in some cases. "In certain instances homorrhage may take place midds the cavity of the tymponum in the same manner and from the same cause as in the nose, mouth, and eyes. If the blood be not alsorbed suppuration is liable to ensue; and subsequently alsorative destruction of the tympunic membrane, as occurs in scarlet fever."t.

The attacks are usually worse at night, and when they rome on the child may get out of bed alarmed, and in terror run round the room in a breathless state. Sometimes the child atmost lie down from fits of sufficiative cough, nor get any rost at night. It is not musual to meet with a child suffering from most of the physical and general signs of bronchitis in whom the poison of whospingrough is not suspected, because the whosp has not been heard. This cough may last when the broughitis improves, and be attended with violent and continuous expiratory efforts, when the look of the child's face and the nature of the cough (coming on in parexjuna, especially at night) are characteristic of pertussis. Nothing is absent but the whoop. This may develop itself further on, or

^{*} In 1878, a toy aged alexen years, of robust frame, come under my rare with alrepting-rough. From the extreme violence of the puresposes, a large efficient of dark blood took place in the left anterior chandler of the eye, only leaving a more speck of the white achieved at its upper part. There was considerable beautiful installing, and some recent amply-series.

[†] Howardsage from the Euro in Whooping-cough; its real cases, by George D. Gala, M.D., Beir Mod, Jurn, 1801, vol. ii, p. 425

nerve be completely developed at all; but the disease is the same, and is all other respects runs its course in the usual way. I have occasionally in practice unit with a case where one shift in a family whooped, and the others, who preximably suffered from the same cough, did not whosp; and I have known the pulsionary symptoms gradually assume the most serious uspect, while the whose has declined, even if it has not been altogether about This is partly to be explained by the temperament and constitution of the shibl. The dread of coughing, or the fear of bring down to sleep, or a fit of pussion or crying, in quite sufficient to bring on a paroxysm. The cough consists in a number of expire tions, and when the child has seemingly forced all the sir out of the lungs (and a considerable quantity is expelled) the effort is succeeded by a long and deep inspiration. As the air passes through the glottis the seculiar sound or whoop is produced, and this sound is liable to great medification. In a little girl under my care in 1874, the inspiration was very elear and lengthened, falling away gradually like the sharp, shrill note of a flute. In other enses it is more barking and crowing. If broachitis is not present in the convulsive or spannodic stage, we may detect no physical changes in the longs beyond a slight light motons rile. Between the fits of coughing the vesicular mornour may not be impaired, and air may enter the minute structure of the longs, as in health ! but during the fit of coughing the lungs empty themselves of six, and none whatever can be heard to enter the pulmonary tisus. When the expirations are long and continuous the child is brought to the verge of sufforation,

A good deal has been recently written on the connection of elemof the freenom linguist with whooping-cough. I have examined a
large number of cases, and I am inclined to agree with those ofservors who regard them as accidental rather than pathological.
When present, they prove the violence of the convolving provyears. As the tengue is protraded from the mouth, its under surface and the framum linguist come in contact with the lower below
teeth, so that these ulcors may be looked upon as the result of
injury. They are absent in mild cases, or where the duration of
the discase is short, or the lower inciser teeth are not developed.

The cough of some children when suffering merely from a ornmon cold is convulsive and ringing; in some it has a deep and somerous sound, which parents attribute to a consumptive origin. and in others it has a croupy character, which they think is the forerunner of croup; but the whosp, when present, is not to be mistaken, and settles all doubts as to the true nature of the disorder.

When whooping-rough has someoded to the oruptive diseases, or has followed any neute illness or long-standing debility, it is difficult to treat and dangerous in its results. When a child has no some recovered from meades than he is attacked by whooping-rough, the two diseases greatly aggravate the danger. Sourcely has there been time for the constitution to recover its lost torol before it is attacked by a occord disease, and so what at first might have passed off as simple functional disturbance, now becomes intensified, and may terminate in organic change.

Nervous symptoms are more rendlly excited in some children than in others, and these cases are always anxious once-in fact, pervetts irritation exerts a powerful influence in many other discases of childhood. Dr. Barnes, speaking of the influence which peripheral irritation has upon the nervous centres of a naturally irritable child, mentions a case of tetands induced in an infant by whooping-cough which came under his own observation. He says, "On January 16th, 1866, I met Mr. Giles, now of Henley on Thames, on the case of a box agod nine months. He had been reased two months, and was taking cows' milk and Robb's hiscrite. He had had whooping cough three weeks, having taken it. from his brother. During the last three days a singular train of errous symptoms appeared; first trismus, then emprosthotomes, the hands ton-hing the feet, then the body arched back into rgistheconos. The fits seemed the first expression of the impulse to ough, the cough coming on men after the fit. Anything in a speen excited cough or fit. The child was not much wasted, but there was some degree of uncernia; the bowels had been out of redor, the atoois pale. Caloniel and rhaburb had corrected this condition. He had had beliadence. We recommended gents' milk, solution of perchlorids of iron, and gave a favorable prognois." The child recovered. "Such a case," adds Dr. Barnes, " unst be studied in connection with the trismus pascentium. It proven very elearly the intimacy of the association between whooping cough and convulsive diseases." This is a truthful maxim

^{*} Loudsian Lectures; On Communic Educates of Women, Brit. Med. Journ., April 196, 1972, p. 424.

which should fix itself on the minds of all medical men. Irritation need only be very slight and transient at the period of the first dentition to originate mischief in one or other of the nervous captres. Convulsive moreoments, stopping short of actual calmination, are exceedingly common at this early period of life. The servous system is so highly organized that any impression on any times or organ of the body is at once felt, and irritation, however varied and remote, freely communicates its infinence to it.

Unless complications arise, such as broughtis, passuments, cerehral or no senteric disease, who oping-cough is not dangerous. Although the disease may pursue a telieus course, and cannot be abruptly terminated by any method of treatment with which we are acquainted, it will somer or later end in complete recovery, if these complications can be warded off.

Generally the amount of spasmodic rough bears no relation to the severity of the broughitis when it is present. In the case of a stramous looking child, five years of age, admitted into the Samiritan Hospital, under my care, in December, 1874, the whooping was very moderate, whilst the broughtal affection and congestion of the lungs were very severe, the pulse reaching 140, and the respirations 56 per minute; the papils were dilated, and the cycliss ordematous. The temperature, which was 102.6" on admission, fell to normal in five days; yet the gravity of the case did not lessen by the fall. The child lay betwixt life soil death for many days, and the restlessness became extreme at night; the cough was excussive, and attended with copious broughful spata; lool mucons rules were heard in the lungs. The visience of the rough led to a considerable degree of employeems of the lungs, and when the child had recovered, the chest was unduly resonant on percussion. Rupture of the nir-cells may lead to an emphysemators condition of the face, neck, and chest. In two cases under my care, a prominent and doughy swelling was situated above the clavides some months after the disease was cured.

The bronchial glands not unfrequently become enlarged in whooping-cough, as they sometimes do in the course of scarintina and mendes. It is supposed by Dr. Gueneau de Mussy, that by the pressure of these glands on the pneumogastric nerve, and particularly on the inferior laryngeal branch, the peculiar quantolic cough is due." But it is important to remember, as Dr. Barlow

^{*} Enlargement of the Broachiel Lymphotic Glauds with relation to Wiscompounds, Brit. Med. Jour., 1979, vol. 75, ps 649.

very truly states, that enlargement of the bronchial glands in whooping cough is not constant, and that they may be enlarged without puroxysmal cough."

3. Fe becomed or fast stage may be described as the decline of the complaint. The cough is an longer so paroxysmal, the spara are thicker and more easily expectorated, and there is no vomiting. The child sleeps soundly at night, as contains ence is ap-

proached, and gradually gains flesh and strength.

Tentered.-Here we have to contend with difficulties. Any contribution that could throw new light on a specify and successful method of treating whooping-cough would be halled with very great satisfaction. Yow diseases are more rebellions to treatment, whether in the acute or chronic stage, and nothing would be more presumptuous than to lay down any plan for-general adoption. Whoning cough, like many other diseases, must be treated on general principles, for we know of no real specific. That plan will be most successful which meets the peculiarities of each case, no two cases being exactly alike, and the epidemic being seldom of the same character and severity. The weakly, stramous child, whose disease is complicated with a pulmounty or a cerebral afficetion, must not be subjected to the same freatment as a strong and healthy child, for whooping-rough is modified by the strength and constitution of the child, by the age, and by the season of the year. When catagglial or inflammatory symptoms provail, or general broughitis is present, our plan of treatment is obvious. If convulsions or threatening symptoms of hydrocephalus should supervene It is equally plain; but to mitigate sufficative attacks of spann, and to cut short this painful disease, we have no remoty on which we can confidently rely,

In cases where breachitis is a prominent feature, and fobrile symptoms are present, cooling aperients and saline medicanes are called for. A mixture containing nitrate of potash, fineture of hypergamus, iperacumha wine, and the solution of acetate of amnonia will be useful. If the febrile symptoms are severe, and the bourle disposal to be obstinate, a few grains of sulphate of magnesis may be added to each dose, which will have an aperient affect and unederate the fever. Sometimes it is necessary to give a good purge, and after it the child is lighter and better. A grain

^{*} Estimated of Breachial Glassis with relation in Whosping rough, it'd, y.

of caloned, and a few grains of scanmony or chalsols, will now and then do great good by emptying the bowels, midding the fever, and relieving the laryngeal space. At an early stage, if the shild in strong enough, we may follow out this plan wish afrantage, and cases occur where it are reeds when specific treatment falls. In this condition we semetimes find the lungs full of loose, scattered broughtal ribes, and the child so prostrate that it cannot stand, the skin bot, the tongue furred, the respiration short, quick, and catching. The susmedic cough and constant expectoration reduce the child's alrength much quicker than in ancomplicated broughitis. The child is now age to become heavy and torpid, and after a fit of cougling and sickness to fall into a drown state from congestion of the brain. When the lips swell, the eyes are heavy and meaningless, and the face becomes bleated from violent energifing and broughtal congestion; it may be necessary to apply two or three beches to the head, and give a grain of calcoud, fidlowed by a scap-and-water enema, if the bowels do not quickly respond.

As the fibrile disturbance diminishes, the nervous prostration and harassing cough are sometimes very troublesons. In this condition explorate of amazonia and spirits of chloroform are newsary to aid the expediention (Form 61); but so long as there is much irritation in the lungs we must be executed in the use of solutives, as I have previously mentioned. In some cases the child becomes much exhausted from the violence of the cough and the copic usuess of the expectoration; the skin becomes relaxed and streaming, a state of positive composition of the whole surface entire, and stupor and drowsiness set in. Here the exhibition of solutives would be dangerous from more points than one, and in place of them we must give ammonia and back, and supply the child with natritious fixed in small and repeated quantities.

When we have successful in overcoming the inflammatory state, antisposmedic remedies are valuable, the dist being carefully regulated, and the action of the bowels being kept as free as is constant with the strength of the patient. On listening to the elect we may often detert extensive museum riles and a large accumulation of phiegra in the air-passages, and there is necessarily danger lest through declining strength the phiegra should fail to excite rough in the broadchal nuncous membrane. At first it may excite greater cough, but as the child becomes oriented by these points.

efforts the cough fails to come on. The right side of the heart becomes overloaded from obstruction to the uspillary circulation, and a state of passive or venous congestion ensures, attended with prostrution and collapse. I have seen a few cases terminate fatally in this way, death being preceded by cerebral congestion and stuper, cold clammy skin, and blueness of the general surface. Sometimes the inflammation spreads to the smaller broads, or to the air-cells of the lung itself, leading to condensation of the lung, even if it does not produce tubercular disease in feeble and haday morrished children.

When the strongth is fairly good, and the patients are harassed by perpetual cough and glairy tensolous teners, we may order a teaspoonful of incommobia wine every ten minutes at bultimo till. coniting messes; but the treatment requires judgment, lest we weaken the digestive powers and lay the foundation for convolsions or some other serious complication. Usually one dose is enough, and the patient falls into sound sleep after it. I have seen the greatest advantage follow this plan of treatment in a large number of cases, when a bromide mixture with bulladonna has been given three times a day, and an americ at night. This jour of making the child sick is of less use if the minute brought are shoked up, and there are any signs of impoded circulation through the heart and lungs, but it is of osperial value where the oppor brenchial tubes are loaded, and the laryax is congusted and britated. Courts austies will sid the expansion of morbid sceretions, subdue the cough, moderate the fever, and rouse the child from stuper and lettergy. If the child has been overdesed with carcotics, this treatment will be the more serviceable.

Diet is of the first importance in the treatment of whoogingrough. It should be light and nutritious. Egg publing, beef tea, and milk are the chief kinds of food to be chosen, because they are digestible and non-irritating. Bread may be given maked in noils; but a small piece of plain bread and butter will often provoke a fit of coughing. Mineral mutters and chicken, in very small quantities, are suitable for children of a certain age, larley-trater, sweetened, and flavored with humon, is an excellent nucliaginous drink. The stomach is very sensitive, and the nerrous system so impressible in this disease, that improper food, end air, or deficient clothing, will be sure to aggravate the com-

^{*} See the action of ometics in Chaps. II and XXXVI.

plaint. A child should always be fed immediately after an attack of cough accompanied by vomiting, so that the food may be digosted and assimilated ore the next paroxysm somes on. If this be not attended to, the food is upt to be comited in the next attack in a partially digested condition, and so is but for all purposes of murition. As far as possible, the most perfect rest of body and mind should be maintained.

The late Dr. Fuller tried sulphate of sinc, in gradually increasing does, to subdue the spassositic rough. "In five only of fiftynine cases in which I had the opportunity of testing its virtues did it fall in giving marked and speedy relief." In no instance did the disease last longer than the eighth week.

In 1858 Dr. Fuller obtained the most satisfactors results from a combination of sulphate of sine with belladoung. He estimated the average duration of an uncomplicated attack to be three weeks or a month. "As soon as the whosp declares itself, a draught is given every three or four hours, containing a grain of sulphate of zinc and a sixth of a grain of extract of belladens. to two drochms of syrup of crange, in from two to six of water; and an additional grain of sulphate of aine, and an additional sixth of a grain of belladonna, are added to each dose daily, or every alternate day, until the quantity taken daily amounts to from six grains to a drawhm of zino, and from two to six grains of the extract of belladouna, according to the age of the patient. To children under a twelvemouth old, I have never administered more than ten grains of the zine and two grains of the belladoora daily, which were given in desce of a grain and a quarter of the zing, and a quarter of a grain of belladonna, every three hours; whilst for children of eight or ten years of age I frequently prescribhalf a drachin, or two scrapous of the zinc and six grains of belladonna."? Beliadonna deserves to rank among the first of our remedies in the treatment of this affection. The excitement and frequency of the cough are allayed by it in a marvellous summer. Large doses of belladonna are well borne by children. But it is important to increase the dose slowly, and if excitement, fevering ness, or breachial engorgement should ensue, then salines and emetics may be called for.

I have not with few instances where beliadonna has not proved

" Jbid., p. 245.

^{*} On Discusses of the Lemm, 1887, p. 1884.

of benedit, and none where it has appeared to do harm. It is of must use in the spasmodlo stage, when the broughful irritation has subsided. I usually begin with a quarter of a grain for a child aged two years, in glycerin or surap of tolu, every four hours. If is has no offeet I give the same dose every two hours until it has made an improssion upon the system. In a recent case I found that the spacemodic cough was uncontrolled till the child, aged eight years, took one grain every three hours. After a few doses the pupils became diluted, the cough issuesed, and the child obtained refreshing sleep. Dr. Barnes observes, "The value of belladouna in allaying spaceaudic or convulsive action is often striking. I have som nothing so effective in the whosping court. of children. Its power over other forms of convulsion is incontestable." But, as I have pointed out, if it is to be of service, we must give it in gradually increasing does till its solutive effects become manifest and the pupils are fully dilated. Like some other remedies employed in this intractable affection, it has obtained no credit, and been looked upon as inert and valueless. This is because the dose given is too small. I can have no doubt of the value of the drug, and at one stage or another I almost usuriably give it. It lessens the frequency and severity of the spannotte attacks in a remarkably certain manner, and subdues the tendency to convulsive movements. When its action has been kept up, and especially when combined with bromide of potassium, if tranquillizes the nervous system, haluces sleep, and relieves the cough.

Sulplate of atropia may be given in place of belladoum, from being tasteless, and the readiness with which it dissolves in water. The dose at first should not exceed the one-hundredth part of a grain. "One-slatteth of a grain of atropia or its salt, given hypodemically, will generally produce slight dryness of the throat or other indications of its constitutional action. Where rapidity of action is required, this is the best method of administering telladount."

Cannabis indies is recommended by some practitioners in the spasmodic stage. One drop of the tincture in a teaspoonful of water, may be given three or four times a day for each year of the child's age.

1 H. C. Wood, M.D., op. cit., 1876, p. 207.

⁴ Dr. Barnos, Lambeira Lectures, On the Contabine Discours of Women, Hrit, Mad. Journ., May 54, 1873, p. 485.

Hydrate of chloral has done good in the spasnedic stage, and relieved the cough, even when specucianha and belladons have falled. Five grains every four boars may be given to a child fire years of age." Of twenty-two cases in which it was contoyed "to relieve the cough, after the whooping stage was fairly reached," in only three did it produce any "approclable benefit."

Croton-chloral has been spoken of as a specific.

Bromido of potassium, like belladoums, is of most calm in the spasmodic stage; and if convulsions or much nervous irritability should complicate the condition, it will be all the more serviceable. When there is much bronchial congestion and ascretion it should be held in reserve, and not given till the lungs are freed of the lead of ploogue by an emetic; but a moderate amount of catarric and bronchitis do not contraindicate its use.

In a hosping-rough when the breathing is excited, brouids of potassium as a relative to the respiratory centre is indicated. On the other hand, when the respiration is labored or shallow, then belindenna is the drug to use as a stimulant to the respiratory contro.

Dr. Dillnberger says, "Some paroxysms of coughing may be alloyed by haying a cold dressing on the lower part of the breastbons, and hence, too, water poured over the breast-hone is reconmended." This treatment is near to me; but we can readily understand that it may exert a tonic and remedial effect where there is an absence of broachial congestion, and the spannodic cough is the chief and distressing symptom. The spannodic paroxysms are sometimes very alarming, and, in a case I saw is 1876, I thought that the child would have been sufficient their violence and frequency.

When a parroxysm of whooping-cough is about to commenter, the head should be elevated, and the child raised up if is bel. Everything about the neck and breast should be lossened. If the child is old enough to understand what is said to him, he should be appropriated and reasoured. The temperature of the room in

the early stages requires to be warm and elevated, as in cases of heraclitis. The tenucious muons must be wiped from the child's neath with a handkerchief; the distress and slarm caused by the little patient's arranget to dislodge it is characteristic, and, from the fear induced, the paroxyam is often prolonged, and the shild much exhausted.

Alone has been considered of benefit by some nutborities in the spannedic stage of uncomplicated wiscoping cough; but I have been to artistled with beliadonts that I have solden employed it. When all fever has departed, or the complaint has become chronic and irksome, it may be given with syrup three or four times a day, in doses of three or four grains. When the brouchial musous membrane furnishes a copious secretion (bronchembon), and the child is getting weak from the cough and sickness, alone seems to act both as an astringent and tonic, becoming the frequency and severity of the parexysms without causing constitution or any life consequences. Combined with beliadones, Meige and Pepper have obtained better results than with any other remedy. They prescribe the undermentioned formula."

I have never tried nitrie acid in the doses recommended by the late Dr. Gibb, but I have frequently given, in the decline of the complaint, the nitromuriatic acid alone, or with tincture of bark, to improve digestion and appetite. Much in the same way, and in

the same states, we should prescribe from

I have rarely given hydrocyanic acid alone. Its specific action is best seen in controlling the severity of the puroxysus, and the frequency of the convolving cough. Its scientive action on the guestic nerves may also have a beneficial effect in allaying the irritation of the digestive organs, and dissionshing the general sensibility of the nervens system; but it will have little or no effect on the cough, if the irritation depends on the accomplation of phlogus in the sir-passages. Here it may be necessary to give an emotic in the daytime as well as at night. To be of service hydrocyanic axid should be given frequently, according to the severity of the

^{*} Formula Co.

Thur there in the require four hours. For a child a year old.

spann and the frequency of the cough. It is a remaily that requires careful matching, for an overdose may produce symaps or convulsions, and it is for this reason that I soldom prescribe it.

When the whoop is duclining, and the febrile symptoms are departing, hydrocyanic acid and quinine are good remedies, and may be given with advantage, even when there is some rhonehus in the lungs, and a little moist crepitation. In three children in one family, who were all select with whooping cough about the same time, I found that in only case the frequent and spasmodic cough was rapidly relieved by this treatment, and they were able to digest sufficient nonrishing feed to strengthen the general system and shorten the duration of the disease. At the end of a week or fortnight, the signs of pulmonary irritation may all disappear, and coddiver oil and preparations of iron will then complete the core.

But among modelines used in whooging-cough the old-fashional remedy of carbonate of potash cannot be ignored. The testimate that has been urged in its favor is very strong. It is of most service when the secretions in the largust are termeious, and adhere to the parts about the glottis, so that they cannot easily be distodged by expectoration. The alicalities of service here, as it is in the only stages of broughitts, when the broughtal numbrane is unscalar, ascreting, and irritable. It controls the violence of the paroxysms which so terribly exhaust the child, and it embies the copious secretion about the air-passages to be more easily distolged. The cochineal usually occabined with the potash mixture is probably of no value, but it is pleasant to the eye, and with syrap will not be refused by the youngest child.

As to the topical application of remedies to the larynx in this intractable disorder, I have had no experience. Sponging the pharynx with a solution of nitrate of silver was long ago altotated by Dr. Eben Watson, of Glasgow, Dr. Horzon Grem, of New York, M. Jouhert, and some other French physicians. Dr. Watson applied it successfully to a buby at the breast, whose life was in danger, and he has given some statistics to show that of sixtysix

^{*} Formula 681

A describe conful energ where or fore lower. For a child two systematics

eases treated by laim, forty-six were cared in a fortnight, and the remaining twenty in three or four weeks. Not one child resisted the treatment. In another calculation, from a severe epidesnic at Glasgour, he gives the proportions of deaths at only 0.6 per cent., and the cases cared within a month were 36.5 per cent." There would seem to be something extraordinary in the rapidity of these eures, because, looking at the experience of most writers on the soldiers, the duration of the disease has generally been much longer, A disease that may end in a fortnight, or extend over six mouths, pursues such an indefinite course that no reliable calculation can he made. If the application of a solution of nitrate of silver (26) to the 30) is such a valuable remedy we are somewhat surprised to learn that it is not more generally adopted. It appears to me that sponging the pluryux and operture of the glottle may give relief, in the purely spasmedic stage, to children of six or seven years of age; but to pass the sponge beneath the glottis into the larvax. which is the only way to not on the secretion which sets up the spasm, must be attended with difficulty and danger. The laryer is very small in young children, and it would require considerable. skill to enter it. Then, too, the alarm and agitation produced by provoke a convulsion.

Dr. R. J. Leet has called attention to the use of carbolic acid in the treatment of whooping-rough. One part of carbolic acid and ten parts of water form a standard mixture, of which two drachms are to be mixed with four ounces of water. This is put into a steam-draught inhaler, and the vapor inspired every ten minutes or quarter of an hour, three or four times a day. Dr. Lee contends that carbolic acid used in this manner is a more satisfactory remedy than any other, and that it has proved of advantage in other diseases of the respiratory organs. Dr. Eurohardt, Lecturer at the University of Berlin, states that in 1878 he used a solution of carbolic acid in water for inhalation three times a day (one and a half to two parts of acid in a hundred parts of water) with perfect

success in the treatment of whooping-rough and other affections of the requiratory organs. Mr. T. D. Harries records several cases of whooping cough which resisted every remedy but carbolic acid. under which the maluly rapidly subsided. It should not only be used internally, but he deposited about the house." Dr. George Rugg, of Cinjum Road, appears to have successfully employed carbolic inhalation as far back as 1898 in the cases of five of his own children. His plan is both ingenious and ready. A few minims of the acid are inserted into the bowl of a tolucospine, which the clobbron smoke. Dr. Rogg, however, is doubtful as to the officery and safety of the remaily, for he says, "the no of earbolle acid is not without danger." He now prescribes a sidetion of elderinated soda with personngunate of potask, in the form of spray, both for inhalation and disinfection; he also funigates the room by means of indine. As brounds of parassimo, beindonna, and an emetic at bedtime are also given, it is impossible to say what share of credit, if may, the earbolic acid inhalation is entitled to. It seems to me that we are dealing with a disease presenting so many local and constitutional variations-space of, congestive, and inflammatory-that no specific treatment and no medicated inhalation will be suitable for every period and stage of the complaint.

In the neurosal stage, quinine and bromide of potassium are very useful; the and beiladonna are also sometimes efficacious, as I have before remarked; but if the languare looked with muera, this must be get rid of before any of these remedies can be of service, for us long as it remains in the broughial tubes it keeps up the cough, and exhausts the child. We must never forget to keep the alient points before us,—the neurosal side is the essential factor in one case, the pulmonary or broughtie in the other.

Any error of diet, and especially overfeeding, fatigue, or exposure to cold, will bring on a return of the symptoms when the

A descriptional three times a day, for a child fee years old.

whooping has entirely disappeared, and we have pronounced the patient cured. The peculiar cough may recur after three months' constion when convulencence has been interfered with.

In the cough which often remains after pertussis, as a form of habit, quinino is most useful. It may be given as the hydrobromate, so with hydrobromic acid, with advantage.

Change of air and locality are very serviceable, and will sometimes effectually got rid of the remaining cough in a short time. In some cases change appears to be attended by no advantage, but it should always be advocated as soon as the disease becomes chronic, and has proved rebellious to treatment. If the general health keeps fairly good, and no complications arise, a natritious and careful diet, with an occasional aperient, is all that is demanded till the malady wears itself out.

CHAPTER XXXIII.

ENLARGED BRONCHIAL AND MERCASTINAL BLANDS.

Course associated with the morbid changes in connection with hypertrophy of the mesontoric giands are those similar changes observed in the bronchial and ouslinstinal glands. The constitutional condition which originates the compulant in both sets of cases is similar; but as the symptoms are necessarily different and often obscure in the latter, I shall devote a separate chapter to the consideration of them.

Before the bifurcation of the traches, in the angle formed by the divergence of the two bronchi, from ten to lifteen lymphatic glands are situated; and glands also exist along the course of the bronchi, chiefly behind them.

Dr. Quain states the important fact, that in health these glands are proportionately larger in infancy than in the adult."

^{*} Director of the Boundard Glauds, Pers. Med. Journ., vol. 15, 1978, p. 961.

Being lymphatic organs, these glands are subject to the same diseases that attack their homologues in other parts of the body, as, for example, that simple strumous subargement as common in the glands in the neighborhood of the sterno-masteid muchs. But, from their situation, any enlargement of the bronchial glands catalle the risk of grave mechanical results. Pressure on a temchus, on branches of the great vessels of the lung, or on the puremognetic nerve, cannot fail to affect most seriously the processes of respiration and circulation. As glands exist in the mediatina, they may from their situation cause, when discussed, complications almost as severe as when the lymphatics of the brenchi are involved.

The cours of hymphatic colargements in the mediasticum and around the brouchi are doubtless similar to the causes of swelling in the glands elsewhere. Thus, unfavorable hygicaic conditions, debility from discuse, starvation, or neglect, may induce the disease moder consideration. Cold and exposure are common exciting ranses of congestion of these glands, or discuso may be provoked by the glands participating in the inflammation of surrounding tissues with which they may chance to be connected, During whooging-cough, the exanthemata, and typhoid fever, the broughful glands are apt to become enlarged. The disease may be mot with during the first dentition; it is intimately connected with strums and tubercle, and the hypertrophied glamb unlarge ensorms degeneration, or even absects and supportation. Its frequency in early life is admitted by mearly all authorities on the subject; yet the observations of Dr. Quain "on young persons and adults show that in fifty-nine cases, twenty-one were make and thirty-six females (in one case the sex was not recorded). Of these, two were under ten years of age, sine were between ten and twenty years of age, eighteen were between twenty and thirty, and twenty-six were over thirty years of ago; while in three cases the age was not stated. If these observations justify any interests, # is that females are more liable to discuse of the broughtal glands than under, and that the disease occurs with increasing frequency after puberty.""

Dr. Goodhart has invisted on the evil effects of overfeeling in association with enlargement of the mediastical glands. Healows

Theorem of the Brenchlal Glands, Eds. Med. Journ., 1878, rol. ii, p. 664.

that this enforced intemperance with regard to diet not only produces disease of the alimentary canal, but "does have in another way; by overstuffing the lymph-glands, giving them more than they can do; choking them with their own materials, and leading directly to takes meanteries, bronchial glandular colorgement, and even, I believe, to a general disease in the glandular elementa in many parts—a process which, at its onset, is more aptly compared to stuffing tarkeys or goese than to any strictly pathological condition."

The physiology of nerve atimulation and reflex action is complex, and in no respect can be more complicated than with regard to the functions of the perves controlling respiration. It is now considered probable that the grave rollex results due to this disorder are not invariably confined to spasm of the laryngral muscles. The mischief appears to lie in the bronchioles and the lung itself, a condition " closely allied," as Dr. Goodhart remarks, " to what we suppose to be the case in spasmodic authma." With the knowledge of this fact, the practitioner becomes aware of the futility of attempting tracheotomy in ordinary cases of unlargement of the broubial glands. But hard-and-fast rules cannot be founded on physiological hypotheses. In very severe and andden fits of dysptors from the discuss now chiming our attention, it may happen that a gland has alcorated into the bronchus, become detached, and produced the same spasm of the glottis which follows the extrance of charry-stones or other foreign bodies into the air-punsages. The well-known fatal case from this cause, in a boy aged olght years, described by Mr. Edwards in the thirty-sixth volume of the Molico-Chiruspied Transactions, and quoted in Holmer's System of Surgery, might have recovered if trucheotomy could have been performed earlier.

On post-mortem examination, the appearances of the affected region are readily made out by any observer who has had a fair idea of the normal size of the bronchial and mediastical glands. From their position (especially as regards those at the root of the lung) it may readily be seen to what extent they press on neighburing vessels and nerves. Dr. Goodhart, in one case, found the preumogastric nerve firmly adherent to a diseased gland. The

^{*} Case of Enlargement or Inflamenting of the Mediastical Glouds, Soit Med. Jurn., vol. 1 1879, p. 580.

patient was a boy, aged eight, who died after suffering from severe paroxysms of dyspaos for a fortnight. The same authority describes an autopey where the thymns gland was found much colorged. The patient, an infant eight mouths old, had been subject to convulsions and fits of choking. Irritation of the meliatinal nerves by the large thymns had probably exercised a considerable share in the fatal result. The tracket and breachi may be alterated by pressure of the glands, and even plugged by them.

The symptome belonging to enlarged mediastical gloods are spannedle fits of coughing, causing lividity of the features, and threatening asphyxin. Other cases begin with catarrh and febrile disturbance, which may had for a week, and then spasmodic cough and crowing inspiration ensue. The child cannot lie down in bed for fear of choking, and he is in constant danger of sufficiency.

The chief symptoms are those of broughial irritation. Wheesing, with attacks of dyspoon, sometimes amounting to spasnotic asthma, is very general in these cases. The fits of soughing are not unlike those of whooping-cough," and in some instances the child some as though it could not get breath, and dies of asphyxia. After death in such cases, enlarged caseons glands are found in the mediastinous, and near the bifurcation of the bronchi. In the ease of a child, two and a half years old, recorded by Dr. Goodhart, a large caseous gland had opened into the trucker, and caused death. The measureric glands were also enlarged, and Peyer's patches were thickened, whilst the muonus membrane generally over this part of the ileum was thickened, and the glands were in a state of overgrowth. In another ease related by him, the thymns gland was very large, and where the inferior laryuged nerve is given off from the par vagum there was an enlarged girad. the size of a "haricot bean," imbedded in the surrounding fiterest tissue. The glands about the root of the lung and vagus were equally large, but not enseous.

An attack of difficult breathing, like asthma, may come on accompanied with lividity of the features, paroxysmal sough, staring eyes, painful unxiety, and end in death by come. In such a case there may be caseous and supportating glands, with broadsprounonia.

^{*} See Chap. XXXII. On Perionic.

[†] Court of Enlargement or Information of the Mediantical Ghada, Eric Med. Journa, vol. i, 1979, p. 542.

I have seen the disease in connection with rickets, acute tuberculosis, and emphysems. The following is a very instructive and interesting case, and the examination after death confirms the diagrosis which was made when the shild first cases under treatment.

C. J, est. 1f. was brought to me on January 24, 1876, at the Samaritan Respital, as an compatient, with the following history: In September, 1875, he was mixed with sough, breathlessness, and febrile disturbance, having been up to this time strong and well. The father and mother were healthy, and there was no phthisis in the family. The shild was pulled, with gray eyes, light hair, and prominent forehead. He had sixteen tooth, which were decayed and rugged, and the gams were red and spongy. The thorax was thin and rounded, and the ribs were very prominent from loss of firsh; beneath both clavicles the percussion-note was hyper-resonant, especially on the left shile; posteriorly the note was tympanitic between the scapule at the upper part, and the breathing was almost cavernous between the spine of the right scapula and vertebral column, but there was no moist cropitation. I diagnosed an empty cavity in this situation. Temperature 1026°; pulse 160, small; respirations 80, short and superficial,

The head was large, and the commover the forchand and templos distended. He was not admitted into the hospital, as the mother preferred keeping him at home. He was ordered a diet of milk and beef ten, and in the shape of mullcine a mixture every four hours, consisting of earhonate of ammonis and tineture of cin-

closs, with syrup of tolu and water.

February 2d.—He was better for a time, in consequence of the directions being excefully carried out, but he relapsed again yesterday
afternoon, was hot, and had beaduche, sweating and perspiration
of the scalp; the child had evidently been in great pain, judging
from the rolling of the head to and fro. The mother stated that
be was always feverish, with flushed checks in the evening; but
the temperature was only 98°, pulse 182, respirations 56. Lond
rhouchus and external sounds were heard throughout the chest,
both in front and behind; there was loose gurgling heard over the
suspected excity or suppurating gland at the upper part of the
left scapular region, close to the vertebra. The child was very
fulgety, irritable, and quarrelsone. Two grains of bromide of
potassium were added to each dose of the mixture, and a tenspoon-

ful of syrup of sensus was given occasionally to keep the bowels frusts open.

14th.—He had greatly improved up to this date, and was much better; had had no feverish attack since the 6th, but his rough was very troublesome, and he was rapidly losing flesh; he was never sick; temperature 99°, pulse 132, respirations 48. The rough was less, and the breathing, though quick, was resier, and more indicative of debility than pulmonary emburrasment; face very pullid, pupils large, eyes bright, skin of arms and legs loose, and both limbs much wasted. To continue the mixture, and take a temposuful of cod-liver oil twice a day.

22d.—The mother feared the child laid whooging cough, as his sister was suffering severaly from it, though she had not heard him whoop; he coughed up much phiegra of a stringy tensions character. He was so restless and freeful that it was difficult to count the pulse. After some treable I made out the temperature in the recount 99.8°, pulse 140, respirations 52. The brounds was

again increased to four grains those times a day.

24th.—Not so well, the cough being too incressant and troublesome for him to obtain any rost or sleep at night; there were loud morous rides throughout the chest, and though he did not whoop, the violence of the cough was suspicious. He was much more manageable, and did not more when the thermometer was put into the rectum. He was ordered three grains of brounds of potassium and two grains of hydrate of chloral, to be taken every night at bestring.

25th.—No rest since last visit; for an hour or two he seemed as though he would lapse into unconsciousness. Though he had not whooped, the cough was incessant and tearing, and the propiration poured off his head. The feet and hands were indicated swell; the eyes had a staring and wild look, and the rolling motion of the head indicated cerebral trouble. There could be no doubt that whooping-cough was a complication.

29th.—He appeared better, and ate some publing, shortly after which he was edzed with a choking cough, turned rather dusky,

and then died suddenly, without any sign of straggling.

Probased to Eccuration (twenty-four hours after death).—Bedy thin and pale, with livid marks posteriorly. On opening the the racio cavity, the large were found to be approximated at the anterior borders, pulid, and very emphysematons, especially the upper lobes. At the upper and proterior portion of the right long, close to the spine, where gurgling was heard when the child first came under notice, was a caseous, supporting broachial gland, from which about a teaspoorful of yellow cheesy matter was approved out; the entire half of this long, when out into, contained many semi-transparent gray granulations, and the whole long-tissue in this situation was pullbd, and of a light roy has; many of the air-calls had ruptured. The left long was more pullid and emphysematous; it contained here and there a few gray granulations and very minute cavities, irregularly and scantily distributed, some the size of a pin a head.

The pericardium contained some thin serious fluid, and the ressels on the outer surface of the heart were full. In the right ventricle was a clot of fibrin, as big as a small walnut, and some dark blood; to it was attached a cord of fibrin, six inches long, with a branch going into the pulmonary artery, and this might have been the cause of smillen death, although post-mortem clots are very frequent in this vessel. The kidneys, spleen, and mesetery were healthy, and no tubercle was detected. The liver was large, extending into the left hypochondrine region; no sign of tubercle.

The brain-structure was soft and pullid; it was considerably enlarged, and the sinuses at the hate were very full and distended, but nothing like allouniness or sere-purelent matter was to be observed around any of the nerves where it is usually seen in meningitis, and no excess of finid was present. The brain, however, was altogether more matery than usual. There was no inbercles anywhere, nor any fluid in the ventricles.

Note.—The immediate cause of death was probably the obstruction of the palmonary and systemic circulations by the outrance of the slot into the pulmonary artery, and so the heart failed.

The next case, though it did not terminate fatally, illustrates all the clinical features of enlarged brouchial glassis.

A. N——, et. 4, was admitted into the Samaritan Hospital on October 29th, 1877. He had been ill three weeks with a bronchial attack and cough. On admission the temperature was 101°, pulse 182, respiration 34. After a purge and a saline mixture the temperature fell to 99.4° in twenty four hours, and two days later it was normal.

The corrient glands on the left side were so large that they ob-

literated the ramus of the lower jaw and filled up the space in the neck. On the right side they were also large, but much less as than on the left.

The patient had a shrill, whistling, choking cough, but varied a good deal in character, being sometimes like croup, and at others resembling a "Punch and Judy" squeak. He was unable to assume a recombent posture, but sat up in led with his head beat His breatling was frequent and notay, and whoming was particularly local after coughing or taking food. Over the upper sternum and along its centre the percussion-note was rerr resonant. The resonance was impaired and the breathing weak under the clavicles. There were loud laryngeal moist somely the respiration was displiraguatic, and the lower part of the sterams was drawn in at each inspiration. Posterioric there was dulican over the upper lobes of the lungs, especially on the right side. between the spine and upper edge of the scapula; resonance was well marked below, but throughout there was ricordus, mixel with large and loose erepitation. Sometimes the respiration was placid and noiseless, particularly in the daytime, but in the evening, or during the night, the breatling was occasionally difficult, and resembled an attack of spasmodic asthma.

The treatment consisted in giving the syrup of lodide of iron, cod liver oil, and good diet. A weak solution of finetane of isdine was applied to the glands in the neck, and between the shoulders at the upper part of the scapule.

The condition varied a good deal for the first three weeks but on the 28th of November the glands in the neck had much decreased in size, and although the face was bloated it was not dusky.

December 18th. The child had in all respects improved; he was lively and cheerful, enjoying his food, and sleeping tranquilly at night. He could be with his absorblers low, or on either side, without causing cough or inconvenience in breathing. The chest was averywhere resonant, inspiration was freer and longer, whilst expiration was much shorter, and there were no moist sounds to be heard, though there was considerable rhouchus. Palse 88; respiration 20. The diminution in the size of the glands in the neck was remarkable.

Caseous degeneration of the broughtal glands has been found in econnection with tuberculosis of the image, as we have just seen. There is a case recorded by the late Dr. Pearson Irvine in which it was associated with tubercle in the lungs, brain, and kidneys, In a log, ad, 7 years, "a tumor" was found beneath the thyroid holy after death as large as a walnut; the broughial glands were swollen and careating, whilst the upper lobes of both longs contained gray granulations, some being small and translating and others larger and undergoing caseation. The lower lobes of the lungs and the kidneys also contained scattered tubercles. At the luse of the skull there were about sight sances of serous officeion, and near the posterior end of the faix cerebri "a mass about the size of a large Barcelonz nut." There were no inhereles at the base of the brain, but they were managens in the corderon, " varying in size from a markle to a small walnut," and they were also met with in the condellum. Notwithstanding these changes, this loy nover experienced any cough from the beginning to the end of his illness."

Another singular case is recorded by Dr Sydney Coupland, the which a caseom mediastical gland barst into the traches, consing feath in a paroxysm of dyspace. The patient, a deficate boy four years of age, was said to be "asthmatical" shortly after birth; later so, when two years old, he had "low fever," lasting seven weeks. When three years old be took cold, and suffered from alarming attacks of shortness of breath, general bronchitis, and hourse ringing cough. Under treatment he became convalescent, and left the hospital. Nine days later he was readmitted with bronchitis, and soon afterwards suffered from paroxysmal attacks of dyspana, inability to fie down, and lividity of the lips. During one of these soizares Mr. Meeris performed trachestomy, which quieted the breathing for a time, but in a month from the date of his residmission another attack occurred, and the child died suphyxinted.

On a post-mortem examination, there was found a collection of strarged and indurated glands in the anterior mediastinum, mostly tear the root of the right lung. In the posterior mediastinum there was a chain of enlarged glands, and above the right brenchus they had formed a mass of rescons matter. "On laying open the tracken, that tube was found to be occluded just above the point

Perk Terres, rol. axix, p. 11. It conserbat recentles Mr. Edvardo's core already period, p. 285.

^{1 16}th, roll are, p. 30.

of bifurcation by a mass of closesy matter extending into the right brouchus, and proceeding from the largest mass in the mediastinus, which had ulcerated through the traches at this point, the aperture measuring nearly an inch along the axis of the tube, while, for more than half an inch above, the calibre of the channel was narrowed by the pressure of the gland from without. There was a ravity in the right agex, the brouchi were dilated, and the lungtions was more or has solidified. There was some enlargement of the mesenteric glands

Freelocal.—This must be conducted on general principles. If there are indications of broachitis or pulmonary congestion, they must be controlled by sedatives and counterirritants; febrile symptoms demand salines and mild aperients (Forms. 7, 8, 12). Carbonate of ammonia, senega, and ipconcumbs should be selected to relieve cough and opproxion in breathing (Forms. 61-66). When the case is not associated with any neute febrile disorders, as tuberele, whooping cough, or measles, but only accompanies loss of flosh and strongth, failing appetite, and general wasting, then cold liver oil, unit extract, and the symp of the iodide of iron, are the remedies host calculated to afford relief.

When bronchial symptoms are present, and there is pain in the sheet, the application of a small lineed positive with a table speciful of nurstard for a few minutes at bedtime may be necessary, the chest being afterwards protected with cotton-wook. Another form of local application consists of a stimulating and solutive liminent, composed of equal parts of aconite and camples liminent, or of belladeana liminear and spirit of obtordors, sprinklad on a piece of finned army out of hot water, and applied under a folded towel or on spongiophine. This will mitem pain in the chest when present, just as it will mitigate the suffering of scintica in adults.

When the enlarged glands have passed into a chronic state, the application of diluted tincture of iedine (1 in 4) may be advantagroundy resorted to. It is remarkable how the hypertrophics ervical and broughtal glands sometimes become diminished in size under the personning use of this valuable absorbent, combined with good diet, pure sir, and such internal remadles as the circumstances of the case may appear to warrant.

AFRICA is one of the most peculiar and intractable of discuss, consisting of a parexysmal form of dyspaces, with tranquil respiration in the intervals of the selzures. It does not necessarily depend upon organic or structural shange in any part of the thoracis organs, and hence it has been looked upon as a purely receass affection; although it would appear that the integrity of the palmentry tissue does become impaired and the heart discussed when the parexysms are frequent, and the complaint is of long continuance.

Neither West, Underwood, Meige and Pepper, Steiner, Churchill, nor Niemeger, alludes to asthma in childheod, which seems to me an emission, seeing that however infrequent it may be at an early period of life, it occurs sufficiently often to require consideration and careful study. Trousseau, Hyde Salter, Thorowgood, and Berkart, enter into the subject of asthma in children. It is rare in hospital practice. I have only seen a few cases, and none of these were under ten years of age.

Cause. These are predisposing and exciting. The disease is

hereditary, running through families with as much regularity as tuberde, or gour itself. It neares in the children of parents who are hysterical, or whose nervous system is highly impressible. To a child so predisposed any exertion or emotion will be enough to invite a parexysus, solely through the effect it produces upon the nervous system, notwithstanding that the lungs themselves are perfectly sound.

Asthma follows whooping cough, broughtitis, and meades; and the inference to be derived from this fact is, that the image in such cases have sustained damage which disposes them to asthum. The bronchial mucous membrane undergoes muse imppresiable pathological change, and its sensibility becomes morbidly increased. "These discuses are, beyond a doubt, the commencer of all the causes of asthma; a large proportion (as much as 80 per cent,) of cases of authors in the young date from one or other of them." "Like all herelitary disorders," says Dr. Fuller, "it may occur at my period of life, and instances are not wanting of its existence is infancy and early youth. One of the most frightful examples of it I ever met with was in the person of a boy thirteen years of age. Insleed, it often dates its origin from the diseases of childhood, from the straining efforts incident to whooping-cough, and the severe bronchitis which acrompanies assales," + Dr. Thorsegood relates the case of a child, aged four, who got an attack of astlons after searlet fever, though there was no anasaren, the prine only contained lithates, and no alloumen. At nine he was still under treatment, and more relief was obtained from a dry bracket air than from any medicins.

The existing causes of asthma are numerous, and they vary in different persons—that which will excite the parexysm in susperson will not do so in another. Trritant substances, such as dust, offensive smells, and cold air admitted into the air-passages in respiration, are common excitants of the asthmatic parexysm; they appear to irritate and effend the bronchial mucous nonbrane, and thus to excite convulsive cough and dyspann. Transeau, who himself was a sufferer from asthma, attributes the worst attack he over had to the dust from eats, which were being measured in his presence, penetrating into the bronchi. He relates cases caused by the thrushing of rice, the shaking of a feather

Str. Asthum, by Tir. Hyde Solins, 1860, p. 120.

^{\$} Discusses of the Longs, 1867, p. 268.

lad in the presence of an asthmatic patient, the olde of speciaanha, lineral, or scanmony, scents of any kinds, the perfume of violets and some other flowers. Senson, climate, and temperature have also a powerful influence in the production of asthma. The smell of cats, dogs, and hare skins, seems to be capable of causing the paroxysm in some persons. Some asthmatic patients cannot steep out of London, and others can only obtain rost in certain districts. Troussessu relates the circumstance of two brothers who were twins, and of remarkable physical likeness. When one had an attack of ophthalmin in Paris, the other, who was in Vience at the time, was also suffering in precisely the same manner. Both more subject to fearful asthma in Marseilles, where they were born; but in Paris they were free. When one was affected the other was also, and both experienced immunity in the same localities.

Irritation of the air-tubes by the inhalation of dust may cause a certain degree of thickening and contraction of the broadial tubes, but it is not of itself enough to procede the asthmatic puroxysm. We know that this is so in mining and manufacturing districts, where workmen are exposed to such inhalation during the chief purion of their lives. The tendency is, however, in them, to effect an alteration in the musons membrane (mechanical broaditis) and the structure of the lungs, and not to produce spannedle currowing, and the resultant asthma. Certain indigestible articles of diet, as choose and nots, may, by irritating the premognistric nerve in the stomach, excite reflex spann in the horizant tubes. In a large number of cases the attack comes on without apparent cause.

The influence which the stomach exercises in provoking an attack of asthem is very remarkable; but it is no more than we might expect when we consider that there is a close connection between the lung and the atomach through the medium of the pseumogastric. In asthematic cases the stomach is generally irritable and the appetite irregular. Salter relates the case of a little girl, eight years of age, who vomited everything immediately it was availoused, but without pain or tenderness. This continued for years, and caused great weakness and amendation. Nothing, except tenspoonfuls of milk, could be retained on the stomach.

⁴ Clin Hall, vol. 1, 1807, p. 630.

At length the veniting crased and authors began. The irritation was transferred from the gastric pertion of the pneamogastric to the pulmonary pertion." Eating late in the day will sometime provoke a paroxysm, while an early dinner, and taking no solid food till next day will ward it off:

Symptoms.-The child, as is the case with an adult, may seen to retire to bed in good health, and an attack may come on in the night, which is the most usual time." The patient drops off to sleep, and after an uncertain interval wakes up frightened with an attack of dyspaces and inability to get his breath. Pain, or a some of constriction is felt across the chest. He feels suffocated, and is anxious to get all the air be can obtain; hence he may rue to an open window, or he at least sits up in bed with his arms thrown backwards, or he kneels, or is propped up in a chair, with his thorax and clavicles fixed and drawn upwards. The face is flushed or of a pule livid hue, and fearfully auxious; the skin is bathed in sweat, the eyes are staring and preminent, and the extremities cold. The pulse may be rapid, and the respirations 60 to 76 per minute. The chest is elevated, rounded, and resonant, with scarcely any expansible movement; the epigastrium is retracted from elevation of the disphragm, whilst the lower rils are retracted during inspiration. The expiration is prolonged and wheezing, the inspiration is short, frequent, and nonstines convulsive. Somerous and abilant rhought usury the pince of the normal respiratory murniur.

The fit may last half an hour in mild cases, or two or three hours in severe ones. Then it pastes off, the face assumes a natural appearance, and the child is himself again. During the fit the urine is copious and clear, but when it has terminated it is scanty and turbid. Sleep generally follows the attacks. A sense of heaviness, weight at the chest, and despeptic symptoms succeed, to be followed night after night by similar attacks. The frequency of return is uncertain, the interval may be weeks of months; in exceptional cases years may slapss.

The disease often begins with enturrh, constant succeing, running of the eyes and nose; and these symptoms may have preceded the asthmatic puroxysm by some days. This is frequently the case with children. In these cases there is argent dyspers and

^{*} Op. car., p. 211.

[&]quot;In some cases the attacks are discoul instead of metomal,"-Transita-

inability to lie down; the normal respiratory marmur is replaced by scorous and mucous rheachi, which gradually constafter the paraxysm is ever.

Tronsseau describes a case of an opposite character in a child. "The patient was a Mobilavian boy, aged 5, who had very distinct and wall-characterized fits of asthma, together with some pulmonary emphysema. In his family history there was no mention of any hereditary tains of goat or of theamatism. I saw him again two years afterwards; he had then a most characteristic fit. of the goat, with redness, swelling, and pain in the big toe. This was the first, and has been the last instance I have over seen of goat at such an early age. The goatty arthritis attacked the kness, and had not the slightest resemblance to neure articular rhountailses. During this attack of gout the boy laid not a single peroxysm of asthmer. The disease ran its aveal course, for, as I will tell you by and by, good and asthma are often manifestations of one and the same diathesis, and they may alternate in the same individual, as they did in my Moldavian putient." Asthmatic sexures have owed their origin to albamanuria and pulmousry. udona, accompanying some forms of Bright's disease t

Diomasic. When there are inflammatory symptoms present in the broadfal tubes, and a great deal of secretion is poured out, the real cause of the dyspanea may be overlooked; but it will be generally found, on careful examination, that the fever is slight, and has no comparison to the local trouble; the paroxysms room at presertain intervals, and they often terminate very rapidly. The respiration is calm and undisturbed between the paroxysms. The dyspects of asthma begins gradually, reaches its zeros, and then declines; the dyspaon of heart disease is generally sudden and due to exertion; it is alarming, and when it has subsided, the patient is not so well as a person after an asthmatic attack, trho will be able to go about his duties as though nothing had happened. A patient suffering from heart disease cannot do this. An adult with a delicate heart, or a child with mitral disease, cannot run operains, or walk up a hill without becoming breathless; but it is not so with the asthmatic, for when the paroxysme soff, his resparation is then free enough. It is important to bear these distisetions in mind, because heart disease is common enough in chibiren. If asthmes or heart disease be complicated with emply-

^{*} Operitor p. 621.

sense, the diagnosis may be more difficult. A certain degree of simphysema probably complicates all asthma of long standing; although it has nothing to do really with the cause of the disorder, being rather an effect of it.

Dysports of an intermittent character, it should be remembered, is also associated with cerebral disease, but the history would prist to its right cause. The irritation of dentition is capable of causing some asthmatic fits. In cases of enlarged broughtst glands pressing upon the vagus and mediastical nerves, attacks of dysport and difficult breathing, not unlike spasmedic asthma, may arise, but these cases eight not to be confounded with geneine spasmodic or breachial asthma, which solely affects the structures conserved in the paroxysm. An asthmatic paroxysm arising from this cause would be likely to cease as the child grew older and recovered strongth.

Propossis. - This is greatly determined by the age and constitution of the patient. Dr. Hyde Salter states that the tendency in young subjects is almost invariably towards resovery; and that under the age of atteen, if there is no organic disease, we may generally predict a favorable issue. This arises in a great measure. from the power passessed by young persons to throw off disease; and that in the intervals of the sciences the bronchial congestion completely passes off, and the capillaries again recover their but tone. Then, too, the disease does not hist so long as is generally the rule in adults, and moreover the "nervous irritability" in whildren, which diminishes as they grow older, also favorable influences the prognosis.) If it is found that residence in some favored to vality keeps off the attacks, while only errors in diet being them on, then the patients have the cure in their own hands. But if there is heart disease or emphysema, and the asthmatic seitares have recurred so frequently as to induce chronic broughitis and impeded breathing then the complication is serious. A recent writer is less hopeful of a favorable termination. He says, "A complete recovery is possible only in children in whom the discuss is produced by a simple hypertrophy of the breachial glands, as this enlargement occasionally subsides and the irritability of the lymphatic system also diminishes towards puberty. But this

⁵ See Chap. XXXIII, (b) Enlarged Broachiel and McClastical Glards.

[†] On Arthura, \$100, p. 274.

invocable issue is very rare, and there are few instances in which children have been known to I grow out " of their complaint."

The presence of inherentar or renal disease will increase the gravity of the progressis. In these cases the dyspoeta is permanent. It may be here mentioned, however, that the coexistence of spaniedic asthms and consumption is very rare, so rare that some authorities have denied it altogether. Dr. Fuller mentions three cases, and I have seen one. "The atmost that can be truly stated in that asthma does not predispose to consumption, nor tubercular discuss to spannedic asthma."

It is extremely rare for the disease to terminate fatally in a paroxysm. Hyde Salter never witnessed a paroxysm prore fatal \$ It most usually seems out the patient by causing obstruction to the circulation, and inducing organic disease of the heart and large.

Forbodys.—The essential cause of anthom is a spasmodic contraction of the muscular walls of the bronchial tubes; and hence the inspiration becomes difficult because enough air raunts be drawn into the pulmonary tissue to properly agrate the blood, the forced muscles of inspiration, such as the scapular and pertoral, are therefore brought into play, and the disphragm is more or has on a plane. Most competent observers now admit the existence of arcular amsociar fibres in the smallest bronchial tubes, and they have also clearly shown that irritation of the pur vagum will exrite contraction of these bronchial muscles.

A pulmomry neurosis may be accompanied by moist rhouchi in the langs—an excess of secretion which is apt to lead the practitioner to suppose that there is inflammation, when in fact there is now. This condition is frequently overlooked in nervous and delicate children; in the rickety it is by no means uncommon to get benealial sounds of a persistent character following slight catarrh. The secretion from the mucous membrane is considerable, and there is wheezing and harried respiration, and yet there is no elevation of temperature in asthma. It is not an inflammatory, but a truly neurosal disorder, and if we are not enlightened snough to recognize this, and allow the idea of inflammation in all instances to take possession of us, we shall not relieve the morbid state. If a child who is subject to asthma takes cold, and

On Asthma, by J. E. Berkner, M.D., 1874, p. 204.

⁺ Op. dl., p. 370.

gets an attack of broachitis, the broachial inflammation may act as an exciting cause in producing the asthmatic paroxysm, but it has no power to develop it. The spasmodic character of the complaint is very strongly shown by the relief which the inhalation of mulatives so often affends.

The degree of bronchitis alone would not produce the peculiar fit of asthma, which really owes its origin to the spasmodic element. The spasmodic attack is chiefly due to the contraction of the muscular coat of the bronchial tubes. "Even then, under the catarrh, which overlies the normal element so as to mask it, the cosmo of the discuse is always the same, and its nature has not changed." Still it must be conceded that repeated asthmatic teigeness have the effect of thickening, and at the same time permanently narrowing the broughful tubes, by throwing upon them an extra amount of work to discharge. Hypertrophy takes place in virtue of the same law which causes muscles to become larger when their functions are increased. "A certain amount then of thickening, and a certain amount of contraction of the broughist tubes is fairly to be assigned to authors, and has in it its sole and sufficient cause."

Some degree of emphysema is always associated with asthma.

The rooms in which these patients live and sleep about the large and airy, with high ceilings and scanty furniture. If there is not a free supply of air they seem choked, and cannot get their breath. Air is what they want, and they are often driven to the open window to obtain it, unlike patients suffering from any other pathonnary complaint. During the night it is all-important that they should have a plentiful supply of pure air.

The next point to attend to is the removal of the neuronal or spasmodic element; the presence of whereing and cutarrhal sounds must not induce us to overlook this important matter, for if we do, and the asthma goes on undetected, we shall not easily subdus the disease. It must be confessed that the remedies are look numerous and uncertain in their effects, one remody answering in one case and failing to afford relief in another.

If there is much secretion and congestion attending the asthmatic puroxysm, then expectorants will be needed; but if there be pure spassu then a residence either in a moist or a pure stear

Treesena, Clin, Med., vol. 3, 1867, p. 633.

[†] Hyde Salter, op. cit., p. 128.

air must be sought. There are, however, many asthunatics who can breathe well in the close confined air of London, but cannot sleep at night out of it. These peculiarities are most difficult to explain. When the system is low and the vessels are relaxed and weak, it is necessary to select a mild climate, so that the bronchial museus membrane may not be irritated, and the general health improved.

Nitrous fames are highly useful in the treatment of asthmawhen the spasmodic element prevails, and there is no broughitis present. The fumes not as an antispasmostic and solutive to the irritated broughial nerves. "The well-known nitro-paper is best made by dissolving four names of nitrate of potash in a pint of het water, and in this should be scaked a perous paper of the thickness and consistence of ordinary blotting-paper. The paper thus made will be strong, forcely-burning paper, and should be kept in a stoppered bottle. When used it must be burnt fast and furiously, so as to fill the room, and commonly it is not till the atmosphere is quite thick with nitrous vapors that the asthmatic gets relief."

If the nitre-paper fails, Dr. Thorowgood recommends that the powdered leaves of stramonium or dry beliadoma leaves be sprinkied on it.† Troussens advises the hursing of stramonium leaves. He relates the case of a child who was always relieved by this method of treatment. The advantage which stramonium smoking has over optum is, that it is a scalative, but not a narcotic. Still, in some cases it utterly fails.

Bellesfense is another remedy which senctimes acts in a marvelless manner. It has a similar action to stramonium in diminishing the contractility of the broachial muscle, and in allaying spasnodic cough. Children, as I have elsewhere stated, bear bellaforms well, and therefore the dose must be gradually increased before we give it up as hopeless. The remedy may be sometimes advantageously combined with bromide of potassium.

Introduce relief; it lessens nervous irritability by its action as a sepressent; it relaxes the bronchial spane, and if there be much raterih clears the larger bronchi of secretion, and in this way proves beneficial. Dr. Salter relates the case of a youth who had

^{*} Letterman Lecrates, On Brownfull Astform, 1879, p. 19.

[†] Op. cit., p. 63. † See Chapter XXXII, On Whosping-ough.

asthma from infancy. The attacks would wake him about forces five in the morning. They were attended with severe dyspace and wheezing, and he was obliged to get out of bed. In half as hour after taking the emetic every trace of asthma had disappeared, and he would then sleep like an infant, and have no remark for a week. The done was twenty grains, and it never failed. Its action was that of a depressant; it produced faintness and muses, and then the spasm gave way and relief came, before it acted as an emetic. By giving the remedy at the commencement of the science we may often out it short, whereas if the milidy is allowed to proceed, and the spasm and broughtst congestion have become thoroughly established, the symptoms are longer in yielding, and when they do there is so much pulmonary congestion and dyspaces that the consequences of the attack are long and tadions.

Tokaco sometimes acts in a similar manner, but it has a tendency to produce more deathly collapse. Autimony has also a similar action, but increasurable is less dangerous.

Hydrate of chloral, by its power to allay spasm, may shorten the asthmatic paroxysm, and quiet the respiration. It is sometimes given with the effect of relieving the wheezing and somous thought.

Coffee is highly recommended by Hyde Salter. He says, "It relieves asthma in two-thirds of the cases in which it is tried." It should be given strong, in small quantities, without milk, and on an empty atomach.? Thereorgood gives instances of great success following the use of citrate of eaflein, in doses varying from one to four grains. It appears to calm the irritation of the nerve centres, to allay excitement, and to promote sleep.‡

Accenie has been found very serviceable in spasmodic asthma. It is a remedy which appears to improve the breathing, to increase appetite and digestion, and to act as a general tonic. Mr. Gaskels, speaking of the relation between proriasis and asthma, says, that a connection existed in at least one-third of the cases. Where the disease is complicated with eccema or provissis, the remedy is

[&]quot; Hosper young the patient, the dass should mover be smaller (Salist). The powder is the most desirable form.

[†] Op. sit., p. 182.

² On the columns of Archen to Skin Discuss, Boyal Med-Chir, Sec., March 889, 1974, Thy Laurer, vol. 1, p. 445, 1974.

very serviceable. The liquor arienticalis may be given in twominim does three times a day after food. It always agrees with children.

Therowgood speaks well of arsenical preparations in spasmodic and congestive authora. He recommends gr. 24 of arsenious acid, or liquor assenicalis well-way, three times a day after food."

Tincture of nux romics alone, or with the tincture of iron, is also useful in some cases. (Form. 53.) The symp of the hypophosphite of lime and Iron is a good remody. Cod-liver oil, by improving general nutrition, ought to be given in suitable cases, especially if the patient he strumous or rickety.

The inhalation of the indide of ethyl, in ten-minim doses three times a day, has been found serviceable in some cases of brenchial asthma, according to Dr. Thorowgood and other writers; but in some instances it cames vertigo and dizziness. It is antispasmodic,

and relieves congestion at the same time.

The inhalation of chloroform has also been employed with great success in arresting a paroxysm. Where the breachial spasm is secure, and the agony is distressing, there can be no objection to trying it if other remodies fail. The inhalation should be proceeded with slowly and cantiously, for it is to be noted that the spasm may yield entirely without insensibility being produced. Temporary relief may also be sometimes obtained by the judicious use of morphia, other, lobelia, or ammonia.

According to Salter opium never does good in asthma. It frequestly does harm by narcotizing and producing sleep, for the binvier and more drower the patient becomes the more likely is

the asthmatic paroxysm to supervene.

Dr. Berkart speaks highly of the use of pilocarpin in the asthratic paroxysm. He says that it attracts to the skin and salitary glands a large volume of blood, and so relieves the congested internal organs by the copious perspiration and salivation which it induces. Where the cardine muscles are weak, or the heart is in a state of fatty degeneration, alarming symptoms may tosse, but the subsutaneous injection of gr. 15, or gr. 54 of atropia som restores the balance. Ten drops of a two per cent, solution of pilocarpin should be injected for an adult, and a loss quantity for a child. The patient should assume a recombent posture (which the speedy relief afforded enables him to do), and the effects of the remoty watched till they have passed away. "Pilacarpin is more suitable in the treatment of the younger asthmaties, but is by no means contraindicated in patients of more advanced age."

Spray inhalations of carbolic avid, iperacuanha, benzoin, cressote, etc., are all useful in certain cases; but in children they are

not very easy of application.

Diet is of the utmost importance. It should be of the simplest description, as roust or boiled fresh meat, chicken, light publing etc., given at regular intervals. If the food be indigestible, or too much be taken at one time, then it is apt to disorder the storach, and to bring on a paroxysm of dyspama. It is, therefore, important to select such a diet for the shild that whilst it appears its appetite it shall contain the necessary matritious elements. If during digestion the food taken undergoes fermentation, and produces distension and fulness, the breathing will be deranged.

A sparing quantity of finid should be taken, and beer and stimulants ought to be avoided. The towels should be kept free by gentle aperients, as a little sulphate of magnesia, or compound liquories powder; and if there are worms in the intestinal caral, the proper remedies should be selected for their expulsion.

Gentle exercise in the open air is most essential when the weather is mild. It brings the muscles into better working order, improves the failing appetite, stimulates the functions of the skin, by which morbid products are removed from the body, and in this way, as the general strength is built up, so the child may possibly

grow out of its disorder.

An occasional warm bath at bedrime will prove of great utility, by relieving the congestion of the lungs and broachi, and in this way will equalize the cutaneous and respiratory functions. Tilman's sea-salt may be added to the morning bath if the child is in a fitting state for it, and the weather is warm enough. These baths act as tonics, and are very useful in strumous and rickety cases.

"In feelde children, especially those whose thorax had been crippled by rickets, gentle gymoustics (Swedish) greatly soint the development of the lungs. Athletic sports, if not carried to exhaustion, are still more useful."

CHAPTER XXXV.

EMPHYSERA.

Two Variantes officerally described. I. The modes. 2. The introduktive—Particular, General Symposius, and Particular States. Calcius and constitutions. The article of positive and constitution of increased benefits as militar are particular described by other constitution of increased argume-Solution and Schmitt intelligence to other completion on proper approximate are present, red-free oil or soil around Dymbolic in the Graduate spream.—Change of air.

WE meet with two forms of this disease, the resission and the interfolular; in the former condition a number of air cells are dilated, and their walls being ruptured and torn they become merged into one, or the alveolar spaces may be simply distended through a less of elasticity, and their ressels atrophied and destroyed; in the latter condition the air-vesicles are ruptured, and sir escapes into the intercellular tissue of the lungs and causes flistension. In resicular emplysems, which is by far the most frequent variety, the lungs are increased in size, while their elasticity is destroyed, so that when the chest is opened their anterior borden are in close contact, and they do not collapse. The surface of the lungs is irregularly elevated from the dilutation of the aircells, but there is no ascape of air into the connective tissue. In this variety a few air sacs may be involved, the whole of a lobule, or even the entire lung. The apices and margins of the base of the lurgs are particularly liable to be affected. The lung-tiesre has lost its creatant feeling to the touch, it pits on pressure, and is coughy, pale, and bloodless; the borders of the lungs come forward, covering the heart, and the liver is depressed, whilst the configuration of the thorax is altered, becoming short, deep, and roundal

Emphysican in its scute form is not an infrequent disease among children, and especially those who are the subjects of rickets and asthma; in the chronic form it is more common in adults. In children who have died of neuto breachitis or paramonia, portions of the long will eften be noticed to be emphysimatous. This, however, is a long and complicated subject, and the reader will ful the pathology fully discussed in the ordinary textbooks.

Interbolator Emplyorus. - In this variety the connective tissue which binds the lobules together is infiltrated with air, which es-

capes into it and beneath the plears, in consequence of the alsvesieles having ruptured. "I have never soon it as an independent affection, but in almost every case where there has been extensive vesicular emphysema I have found the interlobular kind existing to a greater or less extent. It is often very partial, and seems to have little disposition to spread." Some other writers cousider that it is very rarely connected with resieniar emphysema. † Cana in which the plours is raised from the surface of the lung by emphysems are nost frequently met with in whooping-cough, and in one case under my care; the apiecs of the lungs were much involved, producing marked swelling of the neck from the extravasation of air into the cellular tissue. In this form the air-vesicles are rounded, prominent, and movable, and can be squeezed from one place to another between the lobules, and it may even lead to general emphysema. This variety is comparatively rare in children. Whoosing wough is its most frequent cause

Vericules Employeesu-Publishys.-There can be no doubt that the modild changes may be produced by mechanical causes, as in whooping-rough and broodsitis, which causes stretching and dinimulton in the elasticity of the air-sizes, and this without any morhid shange in the lung-tissue itself; still it must be admitted that the disease sometimes creeps on in children who have not suffered from these affections, or any violent cough, as we shall bereafter see. The nir-saes become stretched and enlarged, and finally the clastic fibres give way, leading to perforation and rupture. Fatty matter has been found in the emphysematous portions of the lung, and fatty degeneration assists in the rupture of the nir-cells. In some children it is the result of pulmonary catarrh, but cases occur. in which it appears to arise spontaneously without any bareditary influence, and such instances as those are chiefly met with in strumons and talercular subjects. In some chaldren it appears to be congenital, and in two cases which came under my care in 1876 and 1817, no other cause could be assigned. It often arises in estimetion with pulmonary collapse and bronchitis in children from feecible imponition, and the strain put upon the distended air-

waicles by coughing. It is not commonly associated with pneunoria, and still raror with tuberole or phthisis; but in nearly avery case it may be stated that there is pro-existing disease in some of the vesicles or lobules of the lungs. The bronchial tubes are generally in a state of chronic inflammation, and plouritic adhasines are not rare. The disease tends to produce hypestrophy of the right heart and cerebral congestion.

Symptoms.-The chief symptoms are shortness of breath and dyspress, increased by walking fast, ascending a hill, or going upstairs. At first this is only felt on exertiso, but us the disease advances the breathing becomes accelerated, and even panting when the patient is sitting still. An attack of brouchtal irritation, or indigestion, will aggravate the condition, particularly if there is flatulence, which, however, is more frequent in adults. In many respects the symptoms, according to my experience, are far less argent in children than in adults, and the fits of orthopour and violent pulpitation, which are so common in the latter, are not usual among the former in the most advanced stages of the disease. The sputa are bronchial, and semetimes there is a little blood, from the rupture of small bloodyrasels in the distended ltng tissne. The face is dusky and anxious, and in old standing cases, it has a cranotic tint; the nestrils are diluted, the voice is weak, and the cough foelds; the pulse is weak, and like the respiration, usually slow; the hands feel cold, and the fingers lave a bluish tiet. Headache and drewsiness are common. In some cases emeriation is considerable; the abdomen is large, and as the disease is confirmed the liver and spicen become increased in size. If dropsy occur there is generally tricusoid regargitation. In recent cases complicated with a hooping-ough, the lips are puffed and venous, the conjunctive are watery and injected, and the nose loses its outline from puffiness and infiltration of the suisentaneous cellular tissue; the elavides are elevated, and depressions may be noted above them in some cases. These spaces are sometimes completely obliterated, or they are even prominent and pully, in consequence of the emphysimatous apicis of the lungs forcing their way upwards from the thoracic cavity. The whole thorax is elevated and increased in size at its upper part (barrelshaped), the ribs lose their obliquity, and their anterior extremitics are drawn upwards. The intercestal spaces are widened, and the spine curved with the concavity forward. In the case towhich allocion is made further on, the expacity of the lower part of the chest was much diminished.

The complaint is increased in the winter and spring mouths, and decreases in summer and mild weather. In these cases which are owing to permanent organic change, dry bracing weather

always relieves the respiration.

The respiration is characteristic. The child, like the adult, leans forward in bed with its hands folded, the muscles of the neck, as the scaleni and sterno-cloido-mustofilei, being brought into powerful action, and the shoulders rounded. The most part of the chest is nearly fixed, for the lungs, having already expanded to the utmost, are scarcely affected by inspiration. The lower portion of the thorax is drawn in, and the disphragm in these cases appears passive, and the abdomen flat, or even comave. The respiration varies, however, the thorax, in some cases, being distinctly raised and elecated, and the abdomical muscles forcibly expanding. The inspiration is short and hurried, from the dimisished expansion of the chest, and the expiration is wheering and probugud, because the clasticity of the lungs is besenut. In conversation the shifd waits to get breath if its answers are required quickly, and spasmodic fits of congling are common if the boxchial tubes are loaded with mucus. The character of the locathing is one of the most significant symptoms of the complaint.

A physical examination of the chest reveals bulging of the infraelavicular, mammary, and entire sternal regions. The cirenmference of the thorax is increased, not only because the rila are more horizontal, and the intercretal spaces widered, but the lungs themselves are larger, from overdistension of the siposiries, and the spine is curved forwards, as we have before som. The resonance is so increased as sometimes to amount to tympusites over the whole thorax, the note elicited on percession being much exaggerated in clearness and fulness, especially along the line of the sternum, where the bieders of the lung approximate. This clear percussion sound arises from there being more air within the chest, and inspiration does not, as in healthy lungs, affect it; nor is it diminished by any forced experatory affect. The respiration is weak, rarely raised in pitch, but it may be considerally altered in quality, and sometimes he heard load and superficial, or mixed with albihant rhoughus.

When the lungs are much involved the heart is pushed back-

wards and downwards towards the median line, and the whole cardiac region is resonant, notwithstanding a great amount of hypertrophy of the right heart. Epigastric palastion is often observable. If the heart is simply thrown backwards behind the overlaping long the sounds are weaker and more distant. When it long-standing cases the right heart is modele to empty itself, the unfeato-ventricular valve becomes damaged, and being unable any longer to fully contract on its contents, the walls of the ventricle yield and become dilated, so that congestion of all the internal organs takes place gradually, and this quantity of blood being thrown back on the general circulation, venous congestion is sometime followed by accides and ansarran. But this is rare.

In children, where the disease has been of any continuous, there is often marked anomia and pallor of the surface; they lose flesh and strength, and become sallow and eacheetle as the complaint continues, or there is a fixed remons abrupt color on the checks, as we have before remarked. It is in such cases as these that we often notice that the jugular veins are swollen, the neck broad, and the shoulders elevated.

Emphysima and tuberculosis sometimes exist together, but in my experience the alliance is rare, and no well-marked case has come under my notice for years. Dr. Theodore Williams, Lowever, informs me that it is common enough at the Brompton Heapital.

One of the most marked cases of emplysema I have seen, was that of a girl, act. 11, who was of short stature and very thickly set; her tilde were both curved anteriorly at the lower third, the boul was large and the neek very short. Her face had a distressed and and appearance from cardias trouble, and the thorax presented the following condition: It was deep in its antero-posterior diameter, and much rounded over, and the intercestal spaces in this situation were completely obliterated. The elevation commenced minediately and somewhat abruptly below the clavicles, and was rounded to the night on the right side, whence the ribs sank in; on the left side it was much more bulging and prominent over the whole cardine region, and, in consequence of the hypertrophied and strong action of the heart, the ribs below the miggle were not retracted as on the other side. The upper portion of the lungs, being in a state of emphysema, had forced the heart downwards, as no sometimes see in acetic regurgitation, and had produced collapse

in the lower lobes. The apex beat, instead of being limited to the area of health, was diffused over a large space; long-continued congestion had caused enlargement of the liver, so that its edge could be felt in the epigastrium. The breathing was displayed matic, the upper part of the storoum almost fixed in regulation. though the elacticles and shoulders rose with each inspiration, a slight our-shaped depression being noticeable above the carries. The whole thorax rose at once, instead of the slow dilatation of the chest-walls, as in health. The shiking in of the spigastrium, and the drawing inwards of the lower ribs during impiration, proved that the entrance of air to the whole pulmonary tissue was interfered with, and this sometimes languens in breachitis, causing collapse of the lungs. Posteriorly the chest was much rounded and the sternum arched, and although the child was not stout, the internal or posterior border of the scapule could scarcely be seen." Dr. Steiner says: "The enqueity of the obest is increased, though it does not present the peculiar barrel-shaped enlargement, which is the result of emphysisma in adults."† No better instance to the contrary could have been furnished than this case.

There was a difference in the percussion, and in the character of the breathing over the right back; the note was more resonal. over the greater part of the lung, and the breathing weaker, the inspiration being very short and deficient, and the expiration prolonged. Over the left lung, the inspiration was longer, but not so much so as the expiration; which was musical and wheceleg, and the lung was less rescount throughout. In the right axilla, and as low as the line of the fourth rib, a little faint breatling was heard, but none over the retracted rile or the infra-axillary region indicating collapse. The pulse was 26, respirations 32, temperature normal; no expectoration. The face was not swelled, but the clarks had a deep crimson flush, and the lips were dusky. From time to time, in consequence of the gravity of the heart affection, there was great headache, owing to passive hypermina of the brain; the forelead was hot, and nelied for days together; the jugular veins were swellen, the temporal vessels were full and throbbing, and the child did not know where to lay her head for case. The whole cardine region was resonant, from the edges of

Heart Discose in Children, convented with Valvalue Discose, and with Thomas Delicency, Medical Society Proceedings, vol. in, p. 196, and Medical Press and Circulat, May 7th-Late, 1879.

[†] Discuss of Children, numbered by Lousen Tale, F.R.C.S., 1874, p. 187.

the lungs being emphysematous and overlapping the heart. It was somewhat remarkable in this case that there could exist such a degree of heart disease (triouspid and mitral) with obstruction to the circulation through the langs without any sign of dropsy, or turied urine, the latter secretion being at all times free and healthy.* Indeed, in children I have rarely met with assists or ansauren, but we know the disease, especially with heart affection, is prone to produce these complications.

Emphysema is irrecoverable when complicated with regarde disease of the heart or asthma; but when it occurs as the accompaniment of whooping-cough, it will gradually pass away with the disorder, and the child may grow up without any sign of ever

laving suffered from it.

Transcat.-The pathology of the disease proces that the ruptured lung-tissue is inexpuble of repair, but in slight and recent cases we may do much to arrest further destructive changes. Constitutional remedies are chiefly to be relied upon in these cases, for if we earnot again restore the elasticity of the walls of the air-cells to their normal state, we may prevent, or at least indefinitely retard, degeneration in the structure of the lungs. If there is an absence of renal disease, and the heart is feeble in its action, we must select such remedies as will strengthen it, and improve the quality of the blood at the same time. In the shape of drugs, iron is one of the best remedies for improving the cachexia which is so otten present. The tineture of the perchloride is my favorite form. Dr. Waters speaks well of the ethereal tinoture of the acetate. Strychnia has been employed to increase the tone of the muscular files in the relaxed bronchial tubes, but no positive benefit has ever followed its use, nor has electricity done any good to the damaged pulmonary tissue.

If bronchitis is an accompaniment, and the disease is acute, it will demand for the time being our chief consideration, but the tenselies should not be too depressing. An emetic of sulphate of tite is sometimes useful by relieving the pulseonary congestion

^{*} In confirmed cases of vericular resplayments retail compution takes place, when allowed and constitutes blood are present in the trips. It is in only cases that the terestion is often high colored, and theorem down copions surries are analogy. At other time, in equally severe cases, the trips may be absorbed unit tend clear, and of her specific gravity. When there is a large stall persistent amount of allowers, and the circulation through the large at too much impeded, there is suspicion of organic discount of the kitherys.

and overloaded digestive organs. Where the mucous membrane is dry, and the breathing short, ipsenseusuha and the solution of the acetate of ammonia may be employed, with or without iodide of potassium or chloride of ammonium, to favor secretion. If there is difficulty in expectoration, and of ridding the broaded tubes of nuceus, carbonate of ammonia, spail, senega, and wine will be needed. After this stage has passed away from any again be given.

For the asthum, heart disease, and dropsy accompanying emplysema, the treatment must be directed in accordance with the pre-

vailing symptoms.

Where there is passive hypersenia of the chief internal organs, as the liver, spleen, and kidneys, a scanty diet and free purgation will be occasionally needed. No remedies tend so effectually to relieve the shortness of breath as a grain of calcand now and then, followed by a seidlitz powder, or some saline aperient. After the a gentle effect on the liver may be kept up by taraxacum, with a few grains of bicarbonate of soda, or the nitro-numinatic acid with taraxacum, or calumba (Form 20-42). Quinto and small does of strychnine, to improve appetite and digestion, are to be recommended.

Where the brain is overloaded with blood from passive emgestion, a few leaches to the temples and sold to the head, will be

required before relief follows.

Sedative remedies to relieve cough, if at all violent, must be given (Form. 65-74); they obvious in some degree the congestion of the lungs which is sure to follow continued paroxysms, and prevent the patient from obtaining rest. Sedative inhalations are also useful. The required quantity of chloroform, or nitrite of anyl, conium, or hops, is to be put on a piece of sponge and inhaled through a convenient apparatus, as the steam of het water passes through it, or the medicated fluid may be put into a pint of water at 150°, and the inhalation be continued for about our minutes. The patient should inhale before meals, and should not venture out of doors for some time afterwards. The Electric linhaler, made by Maw, at the suggestion of Dr. Morell Mackensis, is zero convenient."

If the bronchitis and catarrh when present be attended with profuse expectoration, and the child is losing flesh, quining less,

[&]quot; The Plasermoopenia of the Hospital for Diseases of the Throat, 1972, p. 67.

the mineral acids, and cod-liver oil or malt extract, will be beneficial.

Blisters are not required for children, but limiments, turpentine fomentations, and mustard positives may be needed to relieve congestion of the stomach or lungs.

The diet in all chronic cases must be generous and earefully regulated, the food being nutritious and given in small quantities so as not to overload the digestive organs and cause flatalence, which distresses the heart by interfering with the action of the lungs and the descent of the diaphragm.

Gentle and never violent exercise should be reserted to, care being taken to avoid fatigue and to calsu the nervous apprehen-

sions of the sufferer.

Change of air often proves of great benefit.

Two varieties of bronchitis are described, the acute and chronic. The neute frequently follows on ordinary catarrh or cold, which for some days has seized upon the young patient with the wellknown symptoms proviously described,—ramning from the eyes and nostrile frontal hundache, loss of appetite, sore throat, and febrile disturbance. At the end of a few days for the time emnot always be definitely stated; the irritation may have extended to the brouchial museus numbrane, and the child gradually getting worse is unable to leave his bod.

Among the chief causes which invite this affection are coil and sudden changes of temperature (hence its prevalence in the spring and winter months), insufficient clothing, the irritation of dust and naxious vapors; detaility from prolonged suckling, and whatever circumstances tend to reduce the tone of the body, rendering it mable to resist discuss of any kind, more particularly that which is so prone to seize upon the bronchial membrane at an early period of life.

Bronchitis in children may arise from hypertrophy and unleular diseases of the heart, which induce local congestion and disturb the balance of the circulation. It occurs in tuberculosis, altominuria, and some other disordered states of the blood, and it accomponies pretty constantly the various exanthemata. Mondes and whooping-cough are the two diseases with which it is most commonly associated.

In nearles the pulmonary mosous membrane is particularly liable to inflammation, and semetimes it is seriously affected, preducing capillary bronchitis, and even brenchopsessmonia.

The mortality of bronchitis among young children constitutes it one of the most fatal of diseases.

The general symptoms of the acute form depend on the extent to which the respiratory tract is involved. If the larger tubes are principally affected, and the smaller bronchi have coraped, the constitutional disturbance is mosterate, and the child may be up and have an apperite for food; but if the sciance has been sudden and severe, and the smaller ramifications of the tubes are implicated, there may be considerable dyspoora and puroxysms of cough; coated tongue, high-colored urine, elevation of temperature, headache, and thirst. If the obild is old enough to talk, and to express its feelings intelligibly, it will complain of soreness and even pain over the sternum, an irritation in the traches, and a sense of constriction at or about the opigastrium corresponding to the lasertion of the disphragm. The cough is frequent, hearse, and tearing, and it persists whether the child is a swake or asteep, while it will often raise itself up in bed unconsciously, from the severity of the peroxysms, as if frightened, and look about it in amazement. The face is generally flushed and heated in strong children, and there is headache and restlessness, the pulse is full and frequent, the temperature is elevated from 99° to 102° or 103°; frequently it is not above 100°, and in many severe cases when the pulmonary condition denotes considerable danger, it is scarcely raised above the normal standard, though the pulse may reach 140, and the respirations be 50 or 50 per minute, with nowy breathing and prolonged exponition. In these cases the nervous excitement is great, and exhaustion is evident, and there is often a good deal of morns in the tules, indicated by catarrial sounds and lover cough. When the temperature remains low or falls, and the palse and regirations are unick, debility is the chief element to contend with, noises there is enough mischief in the lung to account for the constitutional condition. If the pulse is quick, the respiration is usually quick also, and as the one falls so does the other; but it will often be observed, when there is nothing in the lung to account for it, that the pulse drops in frequency and improves in quality, whilst the respiration remains quick for a considerable time, and only falls to the normal standard as the strength is re-established. In very young children of a few months old, who have never been strong from hirth, there may be loud mucous rattling over the back of the chest, and wheezing at each inspiration; they may vomit all the food they take from the violence of the cough, so that it becomes important to seize the opportunity of giving nourishment immediately afterwards; and if this plan is carried out, many cases that appear hopeless may be saved. These symptoms, which increase in severity at night, and may be followed by convulsions, are not uncommon in cases of bronchitis complicated with whooping-cough,

The cough of children, as of adults, is much influenced by the position they assume in bed. When they sink low down with the bead bent forward on the thorax, the cough is distressing, and though worn out and weary, they are prevented from sleep by the constant and harassing irritation; it is almost useless to restify their position and to raise them up in bed, for they quickly tink down again with the bead buried in the clothes

The character of the cough is not much guide as to the nature of the beauchitis in an early stage, though some writers have attached great importance to it. "A bad sign, furthermore, is when the children cough more when hild on one or the other side than on the back, for this cough in most cases is due to great material alterations in the pulmonary structure. Children with simple bronchitis cough loss in the dorsal decubitus than in the apright posture; no difference can be noted in them between the lateral and the dorsal decubitus." Still it must be admitted that they often get much once when taken out of bed and sursed in the lap.

On a physical examination of the thorax, the chest is found to be resenant throughout, and foud rhoushi of a sonorous character are heard over the upper lobes of the lungs posteriorly, especially between the scapular; whilst the respiration may be clear in the lower lobes. In children of good constitution the disease, even when very sente, does not invariably extend beyond the larger broughi. If the symptoms increase, sibilant rhough) (sounds less hourse and large, but more shrill than the former), denoting impliention of the smaller broads, are heard in the inferior lobes, and there is oppression and weight at the eregastrium. In a day or two, secretion is poured out from the broughi, the cough becomes moister, and the sputa are thin and freshy. If the cough is severe there may be streaks of blood in the expectoration, but it soon changes its character, and becomes semi-transparent, or of a faint yellow color. Later on it is of a yellowish green, and is more viseld and opaque.

Rhowchus and sildus may occur together at the same time, and they generally do, but they may be present independently of each other. The same may be said of the large and small crepitation, the one heard in the large and the other in the small brenchial tubes when there is an excess of fluid in them. Just as sibilus is a more important sound than rhowchus, so is small crepitation than large crepitation, because it denotes the implication of the randications of the brenchial tubes. I have described the course which brenchitis usually takes, but all cases do not run into the moist stage, or that in which crepitation is produced. Now and then the disease stops short of this. Ebonchi and sibili may not proceed further, but be succeeded by the normal respiratory murmur, without any secretion being poured out. All practitious have seen cases where rhonchus and broughial breathing have been

Vegel on Diseases of Children, 1874, p. 284.

the only physical signs heard in the lung. Ringing cough, sorenos of the chest, hurried respiration, flushed face, and fever have been the leading symptoms. Three or four days later the disease had passed away without any secretion taking place. I do not think this is frequent; one or two attacks may end in this way, but subsequent sectures are sure to he followed by copious secretion. In going children, if there is fond rhouchus, it is nearly always speceeded by moist sounds, and the secretion so poured out often cames dyspores and death. In 1869 I attended a boy ten years of age, who had been laid up with cough and febrile symptoms for three days. When I saw him on the fourth day he had becone much worse, his breathing was burried and difficult (40 per minute), nostrils active, face flushed, pulse 100. Loud rhonchus and sibilus with shrill musical sounds were heard throughout the lungs, but percussion was clear both in front and back of the chest, and the heart's someds were normal. There was no history of asthma, but I suspected a certain amount of spasm in the case. A grain of calomel was given on eagur, and a dose of a mixture, containing a few grains of nitrate of potash and a sixth part of a grain of tartarated antimony, every four bours. A poultice was applied to the chest. Next day he was better, and three days later be was well, without any secretion into the air-passages having taken place. A very similar case is described by Dr. Latham.

The next change in severe cases is the disappearance of all glairiness in the sputa, and a purulent mammular condition, which denotes the decline of the disease. This may happen in three or four-days, or it may be delayed for a week or more; and the purulent serretion which we estimate as a most favorable sign may be only slightly marked. Any return of the glairy watery secretion denotes fresh broughful irritation. Congustion of the mucous numbrane diminishes, oppression is relieved, and loose bubbling creptation is heard; but if the disease extends into the vesicular structure of the lungs, the face becomes dusky and anxious, and the breathing is embarrassed. In some cases the secretion is more organized, and takes on the form of croupal exudation, being moulded to the shape of a broughful tube.

When the inflammation is severe, the elasticity of the lungs is greatly impaired, and the lobules becoming distensed and weak-

^{*} Clin Med., vol. ii, New Syd. Soc., 1879, p. 118.

ened, the air is imprisoned and cannot escape. When this takes place the resionlar marmor is abolished, and there is argent dearnon, and whening sounds are heard throughout the chest. The character of the eveptation varies according to the size of the inplicated tabes. When secretion is fairly established, marse, loue, and moist crepitation are heard over the larger tubes, and small crepitation over the smaller ones; and the sounds are so varied and peculiar in some cases as to be whistling and musical-gralegous in certain instances to the rush of air and fluid through a narrow thin tube. In severe cases it is extremely difficult to distinguish the line which separates inflammation of the finer broughan tubes from that of the vesicular structure. The real distinguishing mark is the absence of dulness in the first case and its invariable presence in the latter. The rough in preumonia is much more tearing and painful, the child seems to dread it, the dysposes is more orgent, and there is a further rise in temperature. In young children, the secretion into the brought is essertimes so profine as to give rise to suffocative catarrh and convulsive cough, because the norms is drawn took into the smaller tubes and cannot escape; and when they are so distended no air can be heard to enter the chest. In these mass there is often a good skul of oppression, tightness, and pain at the chest, dyspnera, and restlessness. The child is flushed in the face; the skin is hot or perspiring, and the veins about the nock distended from the circulation being impeded through the right beart; the tips of the fingers are livid, and the countenance is dusky. In severe cases, clots form in the heart or pulmonary artery, the pulse increases in frequency, or is intermittent and feeble, whilst the temperature falls, and the skin is believed with a clammy sweat. There is great danger in this condition, and in many cases the next alarming stage is reached. The child becomes more drowsy and anconscious, and there is difficulty in rousing it to take nourishment. It probably coughs less, though the air-tubes are more loaded, because there is no strength to expectorate; the pulse becomes more rapid and feeble, and the respiration is quick, short, and silent. In constquence of the circulation being nearly arrested in the lungs and the right cavities of the beart, the child may die at any moment from suffication, with convulsions, or coma-

We sometimes meet with acute bronchitis in children of a few months old, who cough and breathe badly for weeks before the affection is fully developed. The children have perhaps been brought up by hand, and are feeble and flatby; they breathe hadly at night from an accumulation of phlegm; the lowels are relaxed, and the motions graenish or white; the respirations are 40 per minute, and the expiration is noisy and whoseing; the pulse is quick, but the temperature not much elevated. The cough may be so great that the food is vomited, and the children waste in corresponder. Bronchitis is assections complicated with laryngismus.

The indications of danger are urgent dyspaces, livid or dusky features, quick pulse, ascenting skin, and failure of strength. In capillary broughlits the danger to life is greater, because the swelling of the tubes interferes with the accution of the blood; and also because there is a great tendency to collapse of the lung.

In some children who have suffered from broughitis for only three or four days, the skin brenks out somewhat suddenly in a chromy sweath the error are dim and the lids half closed, whilst the face is pullid and the lips blue. The child is perpetually restless, drawing up its legs, throwing its arms wildly about, and attempting to turn from side to side. The pulse is rapid and smil; the respirations 60 or 70 per minute, short, shallow, and errirely displaragmatic. The upper lobes of the lungs are fairly resenant on percussion, and the respiration is accompanied with load rhoughns in this situation. Whistling tubular breathing is also heard in the centre and lower lobes, and some purts of the chest-wall are more resonant than others. The shild, even if supported by fixed and stimulants, too frequently relayers into drawsitres and come, or dies in a fit of convulsions. In these cases some digree of catarrhal pneumonia or collapse of the lung may be found after death.

Chronis bronchitis is a sequel to the newle form, or it may result from neglected colds and a low form of inflammation. If the general health has been reduced, or the child is delicate, it is a very element romplaint. Not uncommonly it will be found associated with renal disease. A case of this kind was under my care in 1876, where the bronchial excitement followed desquantive nephritis; then, too, it is often kept up by substructure disease of the lung and dilatation or valvular disease of the beart, which interfere with the pulmonary circulation, and induce congestion of the bronchial ramifications. Strumous and rickety children are also liable to this complaint. When it persists in

salld weather, and in spite of careful management, it should per us on the lookout for tubercle; diffused brought sounds through the chost of any continuance, particularly if the temperature rises persistently in the evening, or is fluctuating, are very suggestive of organic mischief in young subjects. In the cold weather of spring and winter, young children are liable to subscute attacks of bronchitis, with feverishness, wheezing, and troublesome cough, Ehrenchi and loose mucous riles may be heard over the front and back of the chest, and the pulse and breatling are both quickened. If dentition is going on, the appearance of every new tooth is a signal for fresh pulmonary irritation, because the general health is lowered and the child is too weak to resist the changes of weather. When, on the other hand, there is free secretion from the broughtal tubes, with inhitual rough and shortness of breath, the palmonary tissue becomes impaired and emphysema results. This is more common in adults. The tubes become dilated, and the pulmonary tissue shrinks and wastes

Collapse of the lung in one of the consequences of broughitis, and it has been ascerted by some that it may either lead to pasquoria, or to a more serious condition. The collapsed portions of the lung require to be distinguished from pneamonic consolidation; they are not really passumonic, for although of a venues red or plum color, and not crepitating under the finger, they are wanting lufirmness. They bear no traces of inflammatory exudation and sink when placed in water. Moreover, they can be inflated. When the secretion from the broughful tubes becomes engloss and organized, a plug of moons is apt to be carried along one of their ramifications till it is arrested, so that it cannot pass in any direction. In expiration, the air behind the obstruction dislodges it to some extent and posses outwards, but the net of inspiration draws it back again into the tube, where it becomes wedged, and does not permit any air to enter the collapsed lung. "Its mechanism is very simple, and is admirably illustrated by an experiment of Mendelsohn and Tranhe. They introduced a shot into the breschos of a living dog, and the lung beyond the shot became collapsed and thoroughly emptied of air. A solution of gum injected into the brought produced the same result. The air gradually found its way out past the obstruction, and was expelled daring expiration, but was prevented entering again during inspiration. So it is with a plug of tenacious mucus at the bifurearlies of a broachus. It acts the part of a ball-valve in a springe; each explicatory blast may dislodge it so far as to admit of the escape of air around it, but not so far as to prevent its falling back into its old position, and thus closing the passage against the ingress of air during inspiration. This condition of things leads to the emptying and consequent collapse of the air-vesicles beyond the scat of obstruction, with attacks of dysquan, more or less severe according to the size of the period of lung affected, and more or less conducting according to the period which slapses before the obstruction is removed."

Ratiology of Arule and Chronic Bronshills,-In health the inneons membrane of the broach and their smaller ramifications is smooth and uniform, and pours out just enough mucus to keep them moist and lubricated, and to prevent dryness. When from congestion and hyperemia of the membrane, an abnormal quantity of morus is secreted, it accumulates in the brought and dyspara is the result. The larger brought may be alone affected, and the smaller escape, or both may be involved when the disease is much more perious; but it is seldom that all are alike affected, and one lung may be much more involved than the other. The inflamed n uccus membrane is of a pinkish hoe, the vessels are injected and arborescent, and if the attack goes on, the mineous membrane becomes durker, of a dusky scarlet tint, thickened, and of a soft velvery appearance, being covered with mucus. In the broachitis of messies, the mucous membrane is covered with spots similar to those on the skin, and in small-pox postules have been met with in the tracken and larger tubes. The bloodycesels are overloaded, and with increased expolation from the serum of the blood there is an ordematous state of the tissues, and the mucus presents an increased number of cells. The secretion is at first thin and frothy, with a good deal of air; then it becomes tempious and glary, and mixed with purfulent secretion. "When pus-cells present

Vallet on Dissess of the Longs, 1867, p. 125.

I "Ulceration of the manufacture of the tracker and larger branchi, which is community met with in the branchitis of adults. I have mover observed but once. themselves in large numbers, they are probably also to some extent produced by the proliferation of the subspitthelial cells of the connective tissue."

Treatment.-In the neute variety the first step to insist upon in to put the child to bed, and then to direct our treatment according to the age and severity of the attack. If the larger tubes of the lungs are implicated, and there is heat of skin and febrils disfurbance, a warm both and a suline diaphoretic mixture will be advisable, and this, by inducing a free action of the skin and kidneys, may cut short the attack. When the symptoms are of a more serious character, more active treatment will be required. Venesection or breching is narely required. There never found it necessary to employ either in the case of a child, but I can understand that when the respiration is greatly accelerated, and there is so much rhonolous as to indicate great congestion of the vessels. it might prove zerviceable. In children the consitution is usually not robust enough to stand it, and it must not be recknowd among the appropriate remoties. "In children I believe it is never necessary to open a vein, for leaders on the chest form a convenient and effective substitute for phlehotomy." Small doses of fartar emetic, with the liquor amm, seet, (Form, 7), will generally suffice, and if they should excite vomiting at first it will be no drawback. The one-sixth or one-eighth of a grain in solution with the lie amou acet, every three or four hours favors secretion, and lessens the severity of the symptoms. It is important to change the lot day ekin into a maist and relaxed one; and the same applies to the congested mucous membrane of the broachi. Even in these mes it is necessary to be watchful and cautious, as depression and exhanstion may quickly ensus. When antimony is couployed, strong children only should be selected, for a few doses will generally produce a rapid and lowering effect, and they cannot be too carefully watched. Pallor of the face, duskiness of lips, sweating skin, and increased broughial rales are to be looked for, and the local as well as the constitutional condition will grow weese instead of improving in young subjects unless they are vigorous. The vinua antimoniale is generally sufficient to control ordinary cases. In infants and very young children ipseacuanha is preferable, and even this milder remedy should be watched, and combined with

[&]quot; Fennick, Medical ISagamie, p. 45.

[†] B'eller, sp. cir., p. 104.

the spt. ather, nitr, or the liq. asum sect. I have sometimes given hydrocyanic neid in addition to arrest vemiting." If the child becomes pale after a few doses, and the skin is moist and the pulse weak, or if the temperature is falling, it should be discontinued, and ammonia, nourishment, and even wine or brandy employed. In very young children, when the face is dusky, and there is drowsiness, with loose course riles over the chest, there is no better combination than the earlionate of ammonia and spirit of chloroform. Even in these cases I have sometimes known an emetic of iperacuanha and sulphate of zinc have a remarkable rallying office by dishodging a large quantity of bronchial mucus ! A few drops of brandy should be given in milk frequently, or a small quantity of champague in sola-water; water arrowroot, to which brandy is also added, and beef ten, real, or chicken broth, will be demanded. Under this treatment the temperature may fall from 1024° to 100°, and the pulse from 184 to 140 in the course of a few hours. In the case of strong children, with much febrile exditement and athenic action, it may be well to give a powiler of raiomel, James's powder, and mitrate of potably (Form #2). I find this an excellent combination to act on the skin and lowels, exciting free action in these organs, and so reducing the fever and controlling the constitutional disturbanes. Four of these powders are invariably enough in my experience to bring about the desired

result, and it must be understood that the administration of a remody like calomel is only called for under the conditions above enumented. When the disease is limited to the larger broachi, and there is great hypersmin of the vessels, it has an extraordimany effect upon the capillary circulation. Whilst it encourages secretion, it subdues the tendency to inflammatory action, and the plastic effusion which frequently follows it. When the rough is very troublesome, mixture of syrap of squill and syrap of tolu will he useful, and if the bowels are sluggish, syrup of senns may be added. In some mild cases the citrate or bicarbonate of rotash, with speaceanha, will be found a suitable remedy if the torque be conted and an alkali is indicated ! If the bourds are sluggish, a simple soup and water enema, or a drachm of the syrup of service or rhubarb, will be sufficient to excite peristaltic action. The temperature of the room should be 65° to 70°, and in cold weather a broughitis kettle, or the steam of brilling water, to moisten the atmosphere of the apartment, will be useful. When there is much restlessness henbane will be required, or even hydrate of chloral if there is vascular excitement; but this last named fashionable drug, like opium, should be used with caution lost it check the secretion. Chloral, too, requires great care in its employment, as it may depress the respiratory centres and the nervous ganglia of the heart.

The physiological and thempestical action of bridgets of chitical are maintened

in Chap. XXXVIII, On Presumonia.

When the nervous element prevails, as it does in some children, a solutive is useful to procure rest and sleep, and for this end a few grains of the bromble of potassium, with or without the chloral, or even Bover's powder alone, will be serviceable. When the serviceable is freely established, such expectorants as ipcontamina, squill, and senoga will be necessary.* As regards local applications, a turpestine stupe or a warm positive, unde with equal parts of lassed meal and bread, should be applied to the chest or back. In very young children it is an excellent plan to envelop the chest (front and linek) in cotton-wood, and to cover this with oil silk. This zets like a positive, and is far better than the application of stapes and positives, while the child is not distressed by frequent change of ciothing.

I have observed immense relief in many cases from pluring young children as much as possible on the face in bronelitis; but this can only be done with infants satisfactorily. It relieves the cough and respiration, and the tendency of the secretion to gravitate to the lower and posterior surface of the lungs is lessened. The child should be hold across the arm of the nurse, with its facedownwards, and kept for hours together in this position. In the winter of 1876, I attended a child seven months old, with soute betochitis, and I am satisfied that recovery was in a great measure due to the position the child was kept in during the estarrhal stage, when the secretion was copions and the cough exhausting. The child was weak, and at one time unable to cough from the loaded state of the tubes, and the weakness of the respiratory act. There was danger of the elasticity of the lung being destroyed by the accumulation of phicgs in the dependent parts of the chest. I therefore had the child turned on its face, and hid across the nurse's lap in a semi-erect posture. It soon began to improve, coughing up-pldegm easily, and sleeping soundly at intervals. An emetic of ipernenunha in these cuers at bedrings is sometimes ad-

visable, and even at an early stage it may subdue the hypersula of the tules, and shorten the severity of the soute stage."

The duration of the disease is uncertain. It may destroy the life of an infant or young child in forty-eight hours, but the coll-

nary period is from seven to ten days.

Trentucent of Chronic Branchities.-From the onest of the attack it is most important to support the patient's strength. It is sover measury to abstract Mood, or even to employ antimony, though there may be fine bubbling riles, and other signs of bronchial inflammation. To meet this condition we must rely on the administration of ipscacuanha, squills, senega, and nitrous ether. A warm poultice to the chest, or a turpentine fomontation is best and safest, with such stimulants as support the circulation and avert the tendency to sinking and fatal prostration. When the pulmonary bylintion is less active, the earbornts of acumonia and tincture of bark will be found useful.t An occasional emetic to empty the brouchial tules at boltime will promote sleep and insure rest. Alarm may sometimes be caused by children appearing as if they would choke in the net of vomiting, but this never actually happens, and no fear need be apprehended on this greand. I have seen great benefit follow the administration of the syrun of the iodide of iron, with a few drops of ipecacuanhat when there is cough, debility, and free secretion in the lungs. Expecterants alone have an injurious effect, and so artives are equally lad. The necessity of using equam with the utmost caution in young and feelile children, for fear of checking expectoration, cannot be too strongly insisted on. The incessant cough depends on phlegm which has accumulated in the air-passages. Opium renders the mucous membrane insensitive, consequently cough is no longer ex-

Two temporalists three times a day: These proceriptions are suitable for skildren of fire at air years old.

cited, and the child may die applyxiated from the blood not being sufficiently decarbonized. In other and stronger children a sedatire allays irritation and prevents exhaustion, if the condition of the necessa membrane is rather one of irritation and congestion than of free expolation. When the secretion is conjour, and the branchi leaded or chatracted, an emetic of ipecacumha or sulphate of zinc at night is serviceable, and when it has acted well, a stimuliting expectorant and wine should be employed. Cod-liver oil is another remedy at this stage, and is most valuable in obvinting the exhauston and ill-health which so frequently ensur. When the secretion remains profuse (bronchorrhom), and the cough is frequent, quinine, the mineral acids (which are very valuable), iron, conium, and cod-liver oil are most to be relied on. Change of air to a warm equable temperature and a generous diet will get rid of this condition. It is at all times important to attend to the contilation of the sleeping apartments, which should be dry and slry, poither too cold nor too hot, but us uniform as it is possible to make them. Flannel should be worn next the skin, and the first kept warm.

Acure structure, or inflammation of the membrane which invests the long and thornele walls, is a most painful affection, since the inflamed viscoral and parietal layers of the pleura must necessarily rub against each other during inspiration and expiration, so that rest cannot be afforded them. Plearisy when uncomplicated with preumonia is held to be rare under five years of age. Still it must be admitted that the disease is more frequent in early life than is generally supposed; for in the absence of dyspaces the chest constantly escapes examination, and even if it does not, a limited degree of inflammation of the pleara is not easy to diagnose during life.

The disease generally begins with a rise of temperature and rigors, soon followed by catching pain in one side of the sheet, limited to one or two interesotal spaces. If pressure he made over them the patient winces and eries out. The pain commences above and to the left or right of one nipple, as the case may be, and extends through the sternam or up to the axilla. The pala at each inspiration resembles that caused by a sharp instrument penetrating the side. In some cases nearly the whole side is affected. If the disease he complicated with bronchitis or presumation, the physical signs of these diseases are present. There is dyspara and a short dry cough, and the pain is aggravated by each inspratory effort, which is havried and interrupted. The pulse is frequent, hard, and small, and it may be tense; the countemnce is distressed and anxious, and the face sometimes flushed; there is high fever in some cases, but it is not so high as in parameta, and it is more subject to fluctuation; the skin is hot, but most, and the tengue coated; the urine is scanty and high-colored, its specific gravity is also high, and as in many other acute lidarmatery disorders there may be a trace of allormen from venera congestion.

There are exceptions to this general condition, the pain being much less in some cases than in others; it may be absent, and the breathing may be unaffected even when the physical signs tall, cate considerable offusion. Indeed, very rapid offusion of accessity relieves the characteristic pain by preventing friction between the opposed surfaces of the plearer. In some cases quick breathing and debility are the only symptoms which accompany offusion.

Dyspines is a symptom which is apt to misless! the joing practitioner, more importance being attached to it than it frequently deserves. It is often present at the commencement of plearisy, when the pain in the side is sente, and before the edusire stage has been reached. The child does not inflate his lang completely by a full inspiration, because the effort increases the pain caused by the movements of the thoracic parietes, and the pyrexia which is present has the effect of accelerating the respiration. "This dyspoon at the commencement, then, is a false dyspoon, and is not due, like true dyspoon, to defective and insufficient humatosis, but to the pain which limits the respiratory movements and destroys their normal rhythm." Hence it is that as the effusion increases, the pain diminishes, and the respiration scarcely exceeds the rate of health, when the sound long comes into play from spex to base, and takes on additional work.

The position which the patient assumes in bed is a matter of some interest and importance. According to my experience the decabitus is usually dorsal; the patient cannot be on the affected side owing to the pleural friction and the pain which that position entails; on the other hand, lying on the sound side causes discumfors, since then extra work is imposed on the long lying appearance, which requires rest as its pleura is inflamed. Still the shild will assume any position which enables it to breathe with the greatest facility and affords the fullest freedom to the numbered lung.

The physical signs vary with the stage which the picurity has reached, and according to the strength and constitution of the patient. When the picura is dry and inflamed at an carry period of the illness, there will be diminished mobility of the affected side in consequence of the pain experienced on inspiration. The respiratory marmor is weak or indistinct, a rough or grating friction sound is heard from the opposing congested and dry surfaces rubbing against each other. It is a peculiar jerking interrapted sound, as if some structure was suddenly dislocated; the patient's sensations give him the same impression; whilst if the land be laid over the part, a sudden rough jerk is communicated to it as though a rib had slipped over an uneven surface. position where this is usually detected is in the infra-axillary region. The sound disappears when adhesion takes place between the surfaces in apposition, as I have explained when speaking of pericarditis. The percussion-sound is unaltered on the affected side, or at the most the rescuance in uncomplicated pleurisy is only slightly diminished, and the respiration is puccile in the unaffected lung.

In the next stage, or that of effusion, the movements of the

^{*} Dr. Dienlatoy on Dysposes in Arms Plennicy, Gas. Heldom. Sept., 1878.
Qwiel from Med. Times and Gan., Oct., 1878.

observable on the affected side are diminished, varying of crorse according to the amount of fluid poored out. If the effusion is considerable the lower part of the class-wall bulges out, and if very large, there may be a more general enlargement of the affected side, a wider separation of the ribs, and obligation of the intercostal spaces. Vocal framities is diminished in small offusions, and abelished in large ones. The heart is well as the liver and spaces) may be displaced in extensive pleuritic effusions, and seem to pulsate out of its normal position.

In cases of extensive effusion in children whose chest-walls are thin, fluctuation may be detected between the ribs, and the smface is smooth, turso, or even externations. If the chest is examinot carefully from before and behind, enlargement may be detected over the inferior rils of the affected side. This is often very apparent when the child is sitting up in bed, and the physician examines the chest from behind. He is apt to think that the disered side must invariably measure more than the sound one, but there may be considerable effusion without any increase in its dimensions. A large quantity of fluid may be present in one plours without causing the side to become larger. If several ounces are present, the measurement of the diseased side may not exceed the sound one by more than an inch. This is best succetained by using the systemeter. I have had many opportunities of observing this fact in pleuritic effusion of adults, which sometimes results from the pressure of ovarian and other abdominal tumors obstructing the circulation.

The elasticity or power of expansion in the chest-wall depends upon its thickness, the age of the patient, and the strength of the constitution. Hence it is that in shiblings the ribs act with greater freedom, and the ligaments and muscles easily stretch before any force that may be brought to bear on them, such as the pressure caused from within by picuritic effusions.

Andral* speaks of great dilatation of the thorax by the fourth or fifth day of an acute attack; and Dr. Fuller also states that there may be hulging in the lower part of the chest wall before the end of the third day of attack, and that other cases are recorded where the chest is considerably unlarged before the end of the fifth day. "In my experience," he says, "however, this early enlargement has occurred only in childhood, when the chest-walls

Principles and Practice of Medicine, by Sie T. Watson, Bart., 1887, vol. 5, p. 116.

are unusually yielding, and in those children only in whom the costal plears has suffered severely, and in whom the intercostal muscles being paralyzed, and the subserious structure softened and infiltrated with serum, the chest-walls yield to the outward pressure with unusual readiness." In short, culargement of the affected side of the thorax is the rule in cases of extensive plearal effusion during childhood, but is, as I have said before, by no means invariable.

On percussion over the seat of effusion the dulness is absolute. It may be termed characteristic when the fluid beneath is considerable; but in recent cases, when it is moderate in quantity and the long has not suffered much compression, then the note becomes resonant if the patient shifts his position and lies on the sound side. When he lies on his lack, the note is resonant over the front of the chest. When he lies on his face the fluid gravitates to the front, and the note is dull in this situation, though if adherious he present the fluid may be prevented from shifting.

The appearment part of the chest always elicits a hollow sound. when struck, varying of course with every attitude of the patient. This is a valuable diagnostic sign. Again it may be noticed that if the upper portion of the lung has escaped compression and the efusion does not extend above the nipple-line, the percussion-note is so clear as to be tympanitic. Respiration is heard in the affected lang down to the effusion; but in severe cases, when the pleural cavity is nearly full of fluid and the lung is much compressed, the whole side is dull. The respiratory murmur is about, or there is beenelial breatling, with bronchophony along the spine. Of sourse the sounds are altered and modified according to the extent of effusion. Above the line of effusion the breathing is often barsh, tulm'ar, or hollow; yound vibration is increased, and in the interscapular region the respiration may be foul and blowing, and the voice bronehophonic. The unaffected side of the chest is hyperresecunt, and the breathing puerile

In ordinary cases, after three or four days, the pain and fever abute and convalescence begins.

The disease may terminate in resolution, or in adhesion of the two plental surfaces, or in offusion and empressa. But if uncomplicated with tubercle or pericarditis, plentisy is soldon fatal.

The stage of absorption and resolution is characterized by the

clasticity in the chest-walls being regained, and by a return to the normal size. The intercestal spaces lose their distension, and steal vibration returns. The percussion-note gradually becomes clearer as the effusion is absorbed, and the long begins to recover from compression, except where the exultation is thick and plastic, and then the dulaces is permanent. This is particularly the case in the lower portion of the chest, in the axillary line. As regards amenitation, the respiratory number slowly returns, at first weak, short, or harsh, but later on full and complete, as in normal respiration. During this process of absorption, the rubbing of the plearal surfaces one against the other, as at the commencement of the disease, sometimes produces a friction sound, as in pericarditis, when the effused fluid is taken up and the heart comes in contact with the roughened pericardium.

Course.—The disease may follow cold and exposure, a case of which came under my notice a few years ago in a child six years of ago. It may occur in the course of rhonmatic fever. One of the worst cases I ever witnessed was in a buy of twelve years of ago, who was suffering from acute rhonmatism complicated with pres-monia of the left lung. It may happen during one of the examplements, particularly scarlet fever or measles; or be excited by pericurditis, or subcreatiar infiltration of the lung. It may also necompany albuminuria. Dr. West mentions two cases which followed peritonitis.

Diognosis and Propassis.—Plearisy is not generally difficult of detection. The presence of fever along with the neste and catching pain in the side, aggravated by a full inspiration, distinguish it from picurodynia, with which it can scarcely be confounded; and the physical signs clear up its true nature. But the difficulty arises later on when effusion occurs; and then if the case is complicated with broachial congestion, pulmonary tubercle, or broachpneumonia, we may be doubtful as to the presence of fluid. These diseases, however, are most frequently bilateral, whilst a plearitie affusion is rurely so, though serum or pus has been present in both plearal cavities at the same time.

If the outset of the disease is attended with purging, which is not infrequent, and the pain is referred to the abdomen and right hypochendrium instead of the side, and if moreover there is billows venting, our attention may be diverted from the chest to the abdomen; but a careful consideration of all the symptoms ought to prevent us from falling into error. These symptoms, with cough, strong fever, and argent dyspowa, constitute "diaphragmatic plantsy." Plearisy may extend to the perisantium and involve this membrane in inflammation." Like postumonia, the disease sometimes commences with so much headsche and defirium that it has been mistaken for sucephalitis. If there is comiting also, and the cough and pain in the side are slight, and the respiratory normal is simply weak, and no friction sound can be detected, we may overlook the complaint. Still, if we carefully review the whole history of the case, and consider the way in which the disease has commenced, we can scarcely fall into error. As in present in meningitis, the heat of the head is not so great, and there is no squinting or intolerance of light. The child, if old morgh, can answer questions intelligibly.

The difference in dulness between pneumonia and pleurisy is also a great help in diagnosis. In the latter affection it is first detected in the lowest part of the thornelo cavity, and as the disease percoods it is heard over the whole obest, which is rare in prequionia. "The duluers comes on much more quickly in pleurlay than in protunctia. It has been noticed within twelve hours from the tryasion of the disease." + Taking into consideration the interse and absolute dulness of pleurisy, the greater rapidity with which it occurs, and the serous effusion which may displace the least and mediastinum, we have good grounds for framing a diagnosis between the two affections. Oceasionally, we have also another very characteristic sign of plearley when finid is poured out around the larger bronchi, and the lung is compressed by it. The mond then heard is a modification of brouchophony, and is known as orgophicay. It is like a distant tremulous voice when the patient speaks, resembling the squeak of Punch, or, as Laennee uss, like the "bleating of a gost."

When pleurisy attacks a healthy constitution, and is of recent date, the prognosis is favorable; but if complicated with pulmonary phthisis, and the child is of a delicate or rickety constitution, or if there is great debility, then it must be viewed in an unfavorable light.

¹ Disciples and Practice of Medicine, by Sir T. Watson, Bart., 1857, vol. ii, p. 123.

Merkled Anatomy. In the first stage of pleurisy the pleura is drier than in health; its smoothness and transparence are diginished, and its surface is more or less vascular, and covered with floccolli of lymph. In the next stage, or that of efficien, a varialle quantity of serum may be present in the pleural enc, either very transparent, or of a pale lemon-color, or it is sere-purnlent with loose flakes of lymph. In exceptional cases the fluid is of a reddish tint, due to the presence of blood thrown out by the vascular membrane. Layers of thick lymph may also in some cases his seen deposited on the surface of the lung, gining it to the costal pleura, and preventing the movement which normally takes place between them. It is certain that the character of the exulation varies from time to time, according to the health of the patient and the changes that take place in the affected membrane. It marbe serous at first, and then become soro-purulent, or even purulent. Post-mortem evidence of plearisy without postmenia has been detected in the youngest children. The case of an infant a few days old at the Paris Foundling Hospital is alluded to be Dr. Barlow, where two ounces of sero-anguinedent pus were found in the left plenra, etc. Of fourteen cases of plenral effusion under his care, between the ages of sleven months and two years, "eleven were purulent, two were serons, and one was serous with thick lymph.".

Compression of the lang depends on the extent of effusion. If slight it only affects the lower lobe; but if the cavity be nearly full of fluid, and it has been collecting for some time, then it will squeeze the lung against the vertebral column, and increase the dimensions of the chast. In a case of thoracentesis recorded by Dr. Sanson, the lung of a child twelve years of age was reduced to the size of a small lemon, and the pleura was thickened and alcerated. The diaphragm and liver may also be pushed down-

wards, and the heart displaced.

In the stage of absorption the explation that has been thrown out disappears, and the two layers of the pleane unite together by means of the lymph, which becomes changed from a soft structure into a fibro-cellular membrane of variable consistency, in some cases firmly uniting the ribs to the polymonary plears, and it others leaving a distinct space between the points of attachment.

Med. Times and Gaz., December 18th, 1875.

^{*} On Programmy of Pleand P.Suston in Infinity, Lauret, 1978, vol. ii. p. 817.

As the upper part of the sheat-wall is in closer contact with the lung than the lower part, adhesion is more common in this situation; whilst in the latter the offusion gravitates to the lowest part of the pleural cavity, and the ribs net with greater activity.

Iteeducat.—On our knowledge of the exact pathology of each case must rest fundamentally our line of treatment. In most cases a large jacket poultice applied to the side will relieve the pain and relax the inflamed tissues, without the necessity of abstracting blood.

Still I am of opinion that when the disease attacks a strong and healthy shild, and he is seen at an early stage, when the pulse in good, and the pain in the side is severe, three or four beeches applied to the painful part will be likely to arrest the inflammation, and favor resolution; whereas, if depletion is neglected the disease may run into effusion or suppuration, and recovery be difficult and protracted. In a few cases I have employed leeching with advantage, and I do not hesitate to adopt it, as I would in some cases of pneumonia when the inflammation runs high, and the constitution is strong. When pyrexia and pain are felt from the commeacement of an acute effusive pleurisy, Dr. Clifford Allbutt recommends leeching, followed by a saline disphoretic. "At the outset, that is, within twenty-four or forty-right hours, at furthest, tecches should be applied liberally to the parts, seconding to the forces of the patient, and a poultice applied to receive the blending. As soon as the blessling has censed, the affected side should be bound down by strapping, after the manner best described by Dr. Roberts."s

At the commencement of the disease, when the vessels are first overloaded and engarged, a small dose of antimony, given every four hours with the solution of accetate of ammonia, and two or three minims of laudanum (according to the age of the child), will lower the pulse and promote diaphoresis. But antimony is far less beneficial in pleurisy than in poeumonia; and unless the case is complicated with the latter affection, it is quite secondary to calonel and opium. Nevertheloss, free awenting wonderfully relieves the pain, and the remedy is well calculated to out short the high inflammatory fever in a robust constitution. Calonel, with two or three grains of Dover's powder, is a good combination; and

^{*} On the Treatment of Plearitic Efficient, Belt. Med. Journ., vol. 8, 1877, p. 726.

if there is not much pain the mercurial may be given with nitrate of potash and James's powder. (Form. 62.)

An active purgative dose ought to be given at the commencement of the disease to open the lowels, if the pain is not acute enough to be increased by the muscular exertion which it incores. When the pain is severe, our first step should be if possible to arrest it, burness its continuance prevents sleep, and is more exhausting than any depleting measures. It should be an axiom to remove pain at once. "Of medicines," says Dr. Allbutt, "I advise a mild saline pargutive at the beginning, by the use of mercury and chalk combined with the use of Dovor's powder in fractional doses, or in weakly patients by the use of Dover's powder above. Between these powders I give a mixture containing aretate of potash and large doses of liquor ammonize acetatis. By this method I obtain for better results than were wont to follow my expectant treatment of former years. The fibrinous effusion which issues in these cases almost always subsides when it has reached its height, and, if this height he the height of the spine of the scapula and the fourth rib, I am for this reason never in haste to interfere by operation so long as the patient breathes in telerable confort and the other lung is well at work. On the other hand, if the patient be uneasy, or if the entry of blood to the right heart he hindered, I do not heshtate to tap it at once. The favorable aspects of operation in such cases is that suppurative conversion rarely occurs in these highly organized effusions, even if air enters the pleam."

When the sente symptoms have subsided and all fever has departed, counter-irritation to the affected side, in the shape of blisters, with the perchloride of mercury and bark, will get rid of any fluid that may remain. But a blister should not be applied till the chronic stage is reached and the pain is diminishing. Then it does not increase the local mischief, whilst it promotes the absorption of any fluid that may be present. A successor of flying blisters is preferable to one allowed to remain long enough to cause troublesome vesication and screness. For it should be remembered that obstinate sorm and great weakness are prone to follow their use in young children. They should not, therefore, he employed without carefully considering the grave results that may enough.

^{*} On the Treatment of Pictaritic Effection, Bell, Med. Journ., vol. 11, 1817, p. 726.

PLEURISY. 437

The diet in acute pleurisy should be strictly antiphlogistic.

Chronic Plearing.-The causes which usually induce this couldtion are the consequences of the zente form, or of pleuropnenmoula. The effusion which has taken place is slow of absorption, or resists it altogether. If there is fever and the general health is cachectic or much impaired, the effusion may become permasent, and no relief can be afforded except by a surgical operation. Chronic plearisy, however, cannot always be traced to the acute form. It sometimes steals on imperceptibly in delicate shildren, and is only ascertained when a careful examination of the chest reveals the cause of the chronic cough and breathlessness. It may attend the dropsy which follows searlating and renal dieease, or the ansemin of strumous and budly-fed children. It may also arise from the irritation of tubercle exciting a low form of inflammation in the pleura and leading to copious effusion. In these last-mentioned instances the disease is of a subneute or latent. Street.

Pleuritic affusion is most frequently mot with on the left side of the thorax; and the more scrous the fluid the more readily is it absorbed. When paralent or sero-purulent, it disappears very slowly.

The signs that follow the effusion of fluid in the pleural cavity in the chronic state are similar to those of the scute. There are miversal dialness on percussion and an absence of vocal vibration; normal respiration is replaced by bronchial or tubular breathing, ce it may be entirely absent, and dyspaces, accelerated pulse, failing benith, and loss of flesh are to be noted. In some cases there is hertic forcer. The breathing is not always difficult in the absource of tuberely. The offusion may be considerable, and the lung on the affected side may be prevented from expanding; and yet the breathing may be tranquil and cough absent, when one lung is sound and healthy. More particularly is this the case when the effusion has been gradual and the function of the lung diminished by degrees. And it should also be borne in mind that a small effusion may act as an irritant and cause much embarrassment in respiration, when a larger effusion has no such effect. If the effusion is copious, and has lasted for some time, the functions of the lung become gradually impaired or even lost altogether. Both air and lood are forced out of the palmonary tissue by the compression to which it is subjected; and hence the lung, in long-standing cases of effusion, becomes flattened, tough, and contracted. It never completely re-expands, and therefore when the fluid is reabsorbed the chest falls in, the sternum is flattened, the dimneter of the chest is diminished, and the spine is curred. The plears becomes much thickened, and in some cases nicerated. The muscles are more or less wasted, the patient walks much less erect, and leans towards the affected side. The provide respiration in the sound lung, which has been recognized during the effusive stage, leads to more or less enlargement of the air-cells and dilatation of the bronchial tubes.

When the effusion into the left pleural sac is considerable, the apex heat can be sometimes felt to the right of the sterum. "I have observed that in children there is, as a rule, less visceral dislocation than in adults. The displaragm is not so often driven downwards, nor is the heart thrust away so frequently from its position. Their yielding chest-walls expand, and percussion discovers but occasionally that the heart or liver is displaced." In chronic pienrisy, with extensive effusion, the patient cannot lie on the sound side. It is said by some authorities that syncope and irregularity of the heart's action are more common when the effusion is on the left than on the right side. This seems quite possible, for the fibrous adhesions which bind the lung to the spine may limit the heart's novements. "Such bands also, though less frequently, fasten the pericardium in an unmatural position, by which the action of the heart is himbered."

The treatment of chronic plearisy is altogether different from that of the neute form. In the former the diet must be more liberal, and good food and wine will in some cases be needed. It may be necessary to apply a blister from time to time, followed by the application of icdine. The affected side of the chest should be pointed with tincture of iodine, diluted with water (one in seven), night and morning, and then covered with two folds of flamed and calico like a half waisteent in shape. This practice was first advocated by Dr. Fuller.

Indide of potassium with bark, or small doses of perchloride of mercury, squill, digitalis, or acetate of potash may be administered. When the urine is scanty or high-colored, and the effusion is of a

^{*} On Pleastic Effnion, by Dr. Wastell, Bell, Mod. Journ., 1874.

⁴ On Tapping and Draining the Please, by Berkeley Hill, F.E.C.S., The Laurel, vol. ii, 1871, p. 87.

chronic or half inflammatory character, diuretic remedies are of value. Dr. Gairdner speaks highly of cream of tartar electuary in acute and chronic cases of offusion, which not only stimulates the kidneys, but keeps the howels freely open, if they are not already so. It consists of cream of tartar, mixed with equal parts of honey, trendle, or marmatade, and of this a small tempoonful or more may be given according to the age of the patient."

If the child is weak and aniemic we must have recourse to tories in order to maintain the general strength and to promote the absorption of the fluid. Among them the preparation of quinine and iron are invaluable, given alone or in a combination. If the kidners are sluggish in their action, and the tongue is clean, the tincture of the perchloride of iron will prove one of the best of remedies. The syrup of the indide of Iron, the syrup of the phosphate of iron, and the soluble dialyzed iron will furnish good results in some instances. The mineral acids (Form. 14, 20, 21), liquor strychniae, with phosphoric acid, and the tincture of bark, are likewise indicated in special cases. Cod-liver oil should he given in all chronic cases. The skin should be kept in a healthy state by an occasional bath, and even friction over the affected side will in some degree assist in favoring absorption. Above all, the action of the liver and bowels should be efficiently traintained, so that a free elimination of morbid matters may take place through the chief excretory organs.

When the health is sound and vigorous and the effusion is of a serion character, every opportunity ought to be given to promote absorption of the fluid before reserting to thoracentesis.

Emptyone.—This is extremely frequent in children.† When the effusion resulting from chronic pieurisy remains unabsorbed and there is pyrexia, we may suspect that it has become porulout, more especially if there are in addition delirium or profuse perspiration. The fluid becomes transformed into pus much quicker in some cases than in others, but no exact time can be stated with securacy. It remains serous in some instances for weeks together, and in others it is purulent from an early date, probably at the

^{*} Clinical Medicine, 1872, p. 297.

^{8 &}quot;That of first four consecutive cases of pleasing admitted as in-patients at Great Ormani Street, occurs over some congruenate. Taking another series of sixteen case, fourteen were congruenate."—Note in Provide Efficient in Childhoof, by T. Barlow, M.D., and E. W. Parker, Brit. Med. Jones., vol. ii, 1877, p. 759.

are very similar—there is dysprom, increased by lying down or walking, a sense of constriction or discomfort in the chest, and dry and frequent cough with or without expectoration. Generally the face is anxious, or pule, or dusky, the pulse quick and weak, and the pulsations of the heart readily affected in force and frequency by triffing causes.

The physical signs are the same as those met with in pleural offusion, except that there is usually more bulging of the intercostal spaces. Dr. Wilks says, that if after an inflammatory attack in the chest, whether of scute plearisy or of pleuropnessions, "there result localized dulness, with absence of breath-sound, and perhaps distant tubular breathing, an empyema may be safely suspected;" but I think this testimony must be received with caution, even from so high an authority. "It has appeared to us that the aspect of the patient-a peculiar arcmin, with an earthy complexion, and, above all, slubbing of the finger ends, lave been the most characteristic features, suggesting empressa, rather than serous offusion "4 If the effusion is only moderate and not of sufficient standing to seriously impair the resiliency of the Imp. then, as in the serous form, the dulness will vary with the position of the patient, and if he be made to lie on the maffected side, the part of the thorax which before was dull may become resonant in consequence of the fluid gravitating to the lowest part of the ploural cavity. "When the liquid has for a long time been offised, the intercostal muscles, from having been continuously stretched, lose their contractile power, become paralyzed, flat, and then even tend to protrude. Albertini supposed, and Stokes believed, that such a state denoted pas.";

Of all the diagnostic signs of fluid in the chest, whether serous or purulent, the dull heavy thad which perenssion elicits is the most certain. Whenever fluid in any quantity is collected no resonance can be produced; this resonance extends to the limits of the

^{*} Local Empressa; its Diagnosis and Treatment, Brit. Med. Journ., vol. 1, 1878 p. 528.

effusion, varying with the position of the trunk, onless the pleane have become thickened and adhesions formed between them.

It is said that patients ennot lie on the sound side, nor indeed on the other; but I have known them assume any position in bed with considerable fluid in the plears, either serous or parallell, without any oppression in breathing. The absence of this symptom, therefore, must not be relied on as evidence that no effusion exists, and the chest in consequence overlooked.

A case of empyrous came under my notice in a girl, five years of age, who was admitted into the Samaritan Hospital, March 12th, 1878, under the care of Dr. Wynn Williams. She was pale, thin, and deficate, with the fingers much slabbed. The pulse was weak and accelerated, but the temperature was normal. The respirations were twenty eight per minute. It was stated that she had had inflammation of the closet for thirteen weeks, and that two mouths before admission an abscess had been opened, external and two inches below the left nipple, leaving a sinus surrounded by a large granular flabby ulcer. Matter was discharged, and it continued to drain away till her admission.

On examination the left or affected side of the chest was found to be fattened; it measured ten inches from the spine to the centre of the sternum; the right side was more rounded, and measured ten and a half inches. Below the left clavicle the flattening was very perceptible, duluess was great, and no air entered the lung. The left side of the thorax was immovable on inspiration. Through the sinus laudable pus was discharged, and for two inches around il the percussion-note was tympunitic when she turned on the right side, because the pue gravitated to the bottom of the plaural cavity. which now contained air. The respiration was exaggerated over the whole right thorax. Posteriorly the percussion-note was clear throughout the right lung. In the left suprascapular space it was very dall, and respiration was weak and bronchophonic throughout; there was diminished resonance between the spine and the scapula on the left side. No respiration could be heard in the left exillary region. The heart's sounds were normal and very distinct. The apex-heat was seen for an inch to the right side of the left tipple. There was short dry cough, but the appetite was good, and there was no sweating.

On March 23d an opening was made below the angle of the left scapula, and about an ounce of pus drained away through a piece of india-rubber taking. On the following evening the temperature rose to 105.4°, and the pulse to 134. On the 28d the temperature fell to 101.0°, and two days later it did not exceed the normal point. On the 31st am ounce of pus was drawn off through the anterior opening, and a weak solution of indiae injected without raising the temperature. The child left the hospital after a stay of nearly three months, with the sinus still discharging.

The patient again presented herself at the hospital (August 4th, 1879) on her return from the Isla of Wight, where she had been staying for two months. In December, 1878, an abscess which had been forming gradually at the centre of the sternam and in the left of the median line burst, and had been discharging a quantity of thick yellow pus ever since. The two openings previously alloded to healed in February, 1879. The contour of the thorax was much changed in its appearance, particularly laterally and posteriorly. The spine was much curved, chiefy in the donal region between the scapule, the convexity being towards the right side. On the left side the collapse of the lung and the copious discharge of pas from time to time had caused the ribs to fall inwards, and to diminish the capacity of the thorax, so that the infra-axillary region was concave, and the ribs behind drawn in below the left scapula, the angle of which was tilted unwants. The measurements of the two sides of the thorax present a remarkalde contrast :

							(BAg)	14.460A	Ext life.

Line of cariforni									5	-
Line of saillis.							215		2	- 10

Below the left clavicle the note was dull, but some air could be heard to enter it; posteriorly there was resonance throughout the left lung, and respiration was slowly being re-established. Over the old cicatrices air could not be heard to enter from adhesious which had formed there. Throughout the right lung, both in front and behind, the note was hyper-resonant and the respiration paerile. The heart was thrown over to the right side, and its apex felt leating to the right of the ensiform cartilage. There was a distinct apex bruit, which was probably due to displacement and pressure, and also to relaxation of the cavities. The murmust was heard in the back. As the pulse was quiet and the temperature normal, and there was neither cough nor sweating, we may reasonably hope that the last abscess will contract like the two former ones, and the patient eventually recover her health.

When the scate symptoms are of shorter duration the wound may beal quickly. A little girl, aged ten, was admitted into the London Hospital, with signs of effusion in the right plears, pointing beneath the nipple, and cardiac displacement to the left. Although the chest was aspirated from behind, and six onness of pus removed, the skin gave way below the nipple three weeks after admission, and discharged freely. The wound healed completely in two months, and the right chest had fallen in. We must not, however, overlook the fact that a fistulous orifice in the plears may remain open for years, and family contract and heal up. A girl on whom Mr. Berkeley Hill operated for empyema, were a silver tube "from her eighth to her thirteenth year, during which period she had scarlet fever." The core was perfect, heaving very little contraction over the affected side.

An empyema when left to itself may dry up and disappear by absorption. In care instances the pas may find its way through the disphragm into the abdominal cavity and set up peritonitis, or it may perforate the lung-tissue and be discharged through the bronchus, even after paracentesis, and the child then recover.

A case is recorded in which an empyona in a girl, ten years of age, burst into the enophagus.

Paracenteris.—The operation, if indicated, should be delayed till the pyrexin has passed away and the patient is in a quiescent state. But the fact of an elevation of two or three degrees of temperature, fever being present, ought not to stand in the way of an operation, if the fluid is in such quantity as to have resisted absorption, or if it is purulent. In either case the temperature generally falls when the fluid is drawn off, and the potient breather

¹ Ret. Med. Journ., vol. i, 1888, p. 856.

E.Sciner's Diseases of Children, 1874, p. 170.

The Sichery Ringer has recorded some cases of plearatic effection in young rhiblers in which paraceptois was performed with immense relief, and with very little dignations to the general health. Dr. Ringer says his cases show that the operation may be performed thating the Schrile and non-Schrile period of the disease, that the third may be withdrawn by the napitator during the Sener, without my rescursulation; that in some cases of Schrile and non-Schrile compound, a part of the pass may be withdrawn by the aspirator, and the non-Schrile compound, a part of the pass may be withdrawn by the aspirator, and the non-Schrile compound, a part of the pass may be withdrawn by the aspirator, and the non-Schrile compound, a part of the pass may be withdrawn by the aspirator, and the non-Schrile compound, a part of the pass may be withdrawn by the aspirator, and the non-Schrile compound. They further show that in severe empresses the temperature may be normal, or meanly so. (Practitioner, 1875, vol. ii, p. 408.)

more easily, and is in all respects better. The indications which appear to justify thoracentesis are failure in the process of absorption, so that the fluid remains compressing the long, and sanding argent dyspama, irregular pulse, and feebleness of the heart's action; or when the fluid becomes fetid, and produces such contitutional disturbance that the patient is in danger of dying from

heetic fever and septic poisoning.

A case of pleuritic efficient, probably unique from the tenlerage of the patient and the operation of paracentesis, is recorded by Dr. Cayley, where a well-grown male infant, fed at the breast, suffered from cough and difficulty of breathing of one week's duration before any relief was sought. When seen by Dr. Cayley (Oct. 22d, 1878) there was extreme dyspaces and rapid respiration, tossing of the arms about, and throwing back of the load. "There was a frequent abort abortive cough." The whole of the load ing was doll on percussion, and there was an absence of breathwoulds. The beart's apex beat to the right of the sternum. Paracentesis was performed below the angle of the scapula by means of a troom and cannot, and "eight ounces of turbed soram were drawn off by a hell-jar aspirator." A fortnight after the operation there was still cough, but the child appeared well. There was impaired rescence at the left base, and the breathing was tubular,—symptoms not unlike a refilling of the pleural cavity."

After paracentesis, when serum only is evacuated, my fluid that remains behind may become paralent and the patient may dis. As long as the fluid is simply serum every chance should be gives to the persevering use of histors, indine, and other local remains: but when it is paralent, which can only be positively ascertained by passing a gosoved needle, or still better, a hypodermic syrings, through an intercestal space, the somer it is got rid of the better. It is nothing more nor less than an abscess, and must be dealt with accordingly. When put is drawn off by tapping, recovery is invariably slow, because the extensive area of the pleural membrane is in a state of chronic inflammation, and the lung may be bound down through thickening and the formation of false membrane

The operation having been decided upon, an amathetic should be administered, in order to keep the patient quiet and to abeliah pain. I have administered the bichloride of methylene in several

[&]quot; "Plearing with Efficient in an Infant four months old, Paracetamia, Recovery" -Lound, vol. ii, 1878, p. 807.

cases, without inducing the slightest danger, the pulse often improving under its administration. Every child should be anyethedted whose chest requires tapping. The danger arising from it is practically of if carefully administered, and infinitely less than would follow the testious and painful operation of puncturing the glast-wall during consciousness, at a time when the child is already weakened and terrified. Antisoptic precautions are to be adepted.

If the effusion be on the left side it is customary to make an opening in the fifth intercostal space, if on the right side in the booth intercestal space, midway between the spine and the ster-aum (infra axillary region), then to introduce a probe and to pass it democrats to the lower part of the ploural ravity above the displanges. The point having been felt beneath the skin an opening is made upon it, and a drainage tube is palled through, and the two ends united. Simple tapping may be had recourse to if the effection is serous, and the operation may be repeated from time to time, so as to give the cavity a chance of contracting, and the integ of expanding. This has happened in some cases. But if the collection be puralent a permanent drainage must be established.

Another plan, recommended by Mr. Howard Marsh, is to prorue a No. 3 catheter, and by means of a silver wire to push "from the eye to the handle end" a strong silk ligature, hanging out at either end. The catheter is introduced through the upper opening, and its point is directed to an intercestal space at the lowest part of the pleural cavity. An incision is made upon it, the silk wired and held firmly while the catheter is drawn out of it as it was introduced, and a drainage-tube being attached to the silk it is drawn through the two openings."

When the finid drawn off by the aspirator or hypodermic syringe is purulent, and there is accumulation from time to time, a pernament orifice should be maintained by means of a double opening, one anterioriy, and the other below the angle of the scapula, through which a piece of drainage-tube is passed, and secured at both ends in the manner previously described.

During the operation the admission of air into the pleural sac should be carefully guarded against lest it produce suppuration in the sac, "still there is a considerable body of evidence to show

^{*} The Sorgical Trustment of Empyones, Brit Med. Journ., 1977, vol. 7, p. 887.

that the admission of air to the cavity of the thorax, when sarous effusion exists, does not necessarily induce purulence. I may, however, remark that such an accident should be regarded as danger ous; but it is a danger not always easy to avoid, and it should be taken seriously into account among the risks of the operation." Dr. Markham Scerritt prefers the use of an aspirator, as air is thus kept out of the pleand cavity. The best form of aspirator is that in which a special receiver is dispossed with, the tube of the aspirator being set in a plug of vulcanite india-rubber; this can then be fitted into the neck of any ordinary bottle. This convenient modification of the aspirator was introduced by Professor Wood. But whatever instrument we employ, it is certain that Lister's antiseptic method properly carried out renders the admission of ale comparatively harmless. Mr. Berkeley Hill says, "You need not aspirate at all in most cases; the pressure within the chest will drive out the fluid fast enough, though the strings is useful to force luck a clot, or shred of lymph, if such block the tube,"2

The physical and general symptoms which justify the operation

of paracentesis may be thus classified.

 When the effusion has become chronic, the pyrexis has subsided, and the health is perceptibly declining. Under those circumstances death may take place from sufficiation or syncope.

 When the effusion is so large that the lung is compressed and incapable of expanding. This can usually be ascertained by difness on percussion and the absence of respiration, by obliteration or bulging of the intercostal spaces, and occasional increase in the dimensions of the side.

3. When the heart is displaced by effusion, or the liver and spleen pushed downwards, and there is irregularity of the pulse

and dyspness.

 When the effusion remains copious after the assistents employment of constitutional and local remedies, and especially if pus follow the introduction of a grooved neadle into the picural cavity.

 The longer the fluid is allowed to remain in the pleural cavity the more likely is it to undergo pathological changes and to-resist

absorption.

On the Mercality of Plenniny, considered in relation to the Operation of Personal Theresis, by Dr. Wilson Fox, Brit. Med. Journ., 1877, p. 725.

¹ Trestment of Firmusic Efficient Seit Med Journ, 1879, vol. 6, p. 64

¹ Op. etc., p. 88.

8. Fluid may be drawn off as it forms from time to time, lest adhesions ensue, and the lung never completely re-expand. "Contrary to what was once alleged, repented puncture is more likely to prevent the conversion of serum into pus than to hasten it."" The partial evacuation of an empyema may be followed by the draing up of the rest.

7. When the functions of one lung are impaired by the mechanical pressure of the fluid and there is broughitts or pneumonia in

the other.

8. A certain degree of fever does not contraindicate the operation, nor does it necessarily increase the local changes. After tapping, the fever generally falls; and even if heetic fever is persent, the free escape of pus through a good-sized opening in the most dependent part of the chost-wall will cometimes arrest it entirely.

With regard to injections of iodine into the pleural sac, I have known considerable fever and pain follow their use in the most diluted form. When there is a copious secretion of offensive pus keeping up the febrile state, a weak solution of carbolle acid, introduced through a flexible catheter, appears to be highly advantageous. Dr. D. M. Williams washed out the pleural cavity for thirty-one days with a weak solution of sulphurous acid, and a good result followed †

In long-standing cases of empyema the class may be contracted and the ribe approximate, so as to produce great deformity, and yet the pleural envity may be full of fluid, and the disphragm be

pressed downwards.

Empyone may exist with proumothorax, air having found its way into the cavity of the chest through the picura lining the ling, or the interior of the chest. A singular case is recorded by Dr. Cheadle, in which a boy, ten years of age, who was admitted into the Hospital for Sick Children, April 18th, 1877, had effusion in the right picura with displacement of the heart's apex. The temperature oscillated between 19.5° and 192°. Between the time of his admission and the August following he was tapped four times. On the last occasion twenty-six ourses of thick pas were removed. There were fever and swenting, soon followed by phichitis in the right leg, and alight albuminuria. In September a counter-opening was made in the chest, a drainage-tube in-

^{*} Berkeley Hill, op. ch., p. 88-

serted, and the cavity of the pleura syringed out with earbolic acid lotion. Three days before death the respirations became rapid, face bine, cardiac resonance, and amphoric breathing over the left sipple. "At the post-mortem examination the right lung was found completely collapsed, while the pleural cavity was fall of air. A hole, capable of admitting the little finger, and first with lymph, passed through into the pericardium, forming a free communication between it and the pleural cavity. The heart was uncovered by lung, and came up close to the chest-wall; the pericardium was thickened and lined throughout with a thick layer of lymph, as was also the heart, but there were no adhesions. It appeared certain that a condition of pneumo-pericardium existed. There was no sign of tubercle."

PSEUMONIA is a disease about which so much has been observed and written that it would be stronge if its nature and treatment

^{*} Brit Mol. Journ., 1877, vol. ii, p. 387.

were not better understood now than formerly. The most complete attention has been directed to it, and the physical and general symptoms attending its various stages have been carefully studied by physicians and pathologists. If the disease in consequence of this advancement has lessened in mortality among adults, it must still be viewed as a serious one in children. Genuine preumonia in early life is a formidable and fatal affection (even when it is uncomplicated by renal or cardine disease); the argent dyspous, and embarrassed pulmonary circulation, are seen followed by come and fouth if both lungs are affected, or even if one is rendered nearly nicless as a breathing organ.

Paramonia in children is divided into three stages of inflammation, as in adults, and the same pathological appearances accompany each stage of them. I. The stage of expergement. 2. The stage

of red hypotization. 3, The stage of gray hepatization.

In the stage of engagement the lung is of a reddish brick-order approaching to brown, or it is mostled or livid. It is less elastic, heavier, and softer, and this diminution in its consistence has carned the name of aplentication, because it is easily torn like the spoon itself. Some portions of the lung float in water, and others sink from the small amount of air in them, and when a section is made there exades a frothy and viscid bloody serum containing air.

In the stage of red heponication the lung has lost all crepitation, and the weight is increased. It is more solid and distended from the amount of fibrinous exudation, and the nurks of the ribs are sometimes observed where the lung has been pressed against them. The external aspect presents a deep red color, and on section the surface is either murbly or of a grayish opaque has. The granular appearance is the characteristic feature of this stage. Sometimes the cut surface is like a piece of liver. It is produced by the effection of congulable lymph into the zir-resicles, and is not so commonly observed in children as in adults, or when the exudation is softer and thinner. Scarcely any finid escapes except on pressure, which is thick, scanty, reddish, and non-accusted. The lung instantly sinks in water.

In the third stage, that of gray or pellow depatiration, the color of the lung is paler, of a greenish-yellow, or of a light-gray slate, and, as in the previous stage, it is dense and importantle to air. The air-vesicles are distended with inflammatory exudation, and

the long sinks in water. It is also soft and pulpy, and breaks down under pressure of the finger. On section, a gray yellowish fluid (approaching the consistence and appearance of pine) escapes in considerable quantity, and in bad cases the whole long becomes infiltrated with purulent matter, which, if the case terminates successfully, is either absorbed or expectorated. This stage very rarely ends in abscess and gangrene.

"In some cases of preomonic inflammation there is no reddening of the nuccon numbrane of the finest brouchful tubes—no post-mortem appearance to show that there has been anything more than a simple uncomplicated inflammation of the air-sam; whilst in other cases an increased cascularity of the brouchful membrane indicates the consurrent existence of brouchfule inflammation."

Symptoms.-Programmin in its first stage sets in with rigors and shivering, high inflammatory fever, pungent heat of skin, finded face, headache, furred tougue, scanty and high-colored urine, prostration of the strength, quick pulse, thirst, loss of appetite, deep scated pain in the obest, or in our side when the pleura is primarily involved, and a short dry cough. The mode of invasion, however, differs, as we shall presently see. In a day or two the cough is looser, and some adhesive muons is expectorated of a rusty or varuish color, though in children of eight or ten years of age there may not be the restige of expectoration. After this the symptoms subside, the expectoration, if any, becomes uncopuralent, and in the course of ten or fourteen days the patient is our valescent. In other cases the symptoms are more unfavorable; on the third or fourth day the respiration increases in frequency, and if there are spata they are streaked with blood, the pulse is frequent and feeble, the tongue dry or brown, and delirium or come comes on, with the attendant symptoms spoken of as typhick The last stage is announced by finttering of the pulse, accelerated respiration, and a sweating clammy skin. There is semmounce and stupor, and the child is as heavy and indifferent as though he

^{* &}quot;The gray color, indeed, which the long process is due mainly to the named pigment which it contains, and then it happens that a hepatized long is south darker in agod persons, where more natural pigment exists, thus, in children, whom pigment is almost detroiced; then it is that the hepatized large of children is white, it pallers white." (Willia and Morcon), Pathological Anatomy, 1975, p. 325.

Diseases of the Chest, by Dr. Waters, 1873, p. 27.

was laboring under a narcotic poison. As the fatal issue approaches, the cheeks become july, and the lips and extremities of the fragers flusky, whilst the temperature falls, and the pulse is gradually extinguished. The local signs are indicated by fine crepitation, replacing the vestrular marmar in the inferior portion of the lung, with duliuss on percussion, brouchial breathing, and increased vocal resonance. There is paperle respiration in the bealthy long. Dulness on percussion and minute crepitation are the most characteristic signs. If the case pursues a favorable course, the bronchophony and bronchial breathing diminish, or disappear, and large mucous crepitation, or subcrepitant rhonolars takes their place. If the inflammation subsides, the propitation is guidently succeeded by the healthy vesicular murmur, and the long again after an indefinite time becomes resonant on percussion. When resolution does not ensue, the brouchophony and dulnoss increase, and went fremitus is absent. But if one lung becomes so consolidated that no air can enter it, there is an absence of tracheal breathing and bronchophony. If the hepatized long supparate, and matter is discharged, amphorie breathing and pectorilogor, as in a phthisical cavity, are to be expected and watched

Positionia does not follow the same course in all cases; in some delicate and badly-nourished children, one or more absresses may form, which discharge themselves into the bronchi or pionra, or the finid parts being absorbed they undergo calcarcous change and dry up, surrounded by a firm tight membrane. In other cases the formous efficient undergoes contraction and shrinking, and leads to the condition known as circhosis of the lung, or "fibroid plathisis,"

We may now consider the different forms and peculiarities of promonia to which the lung is liable, and these are the following:

distr paramenta (lobar, or ardinary paramenta—crospous paramuis) presents the anatomical appearances just described. It generally attacks the lower lobe of one long (basic paraments) in sluits, but in children it may occur in the middle lobe also, and set unfrequently the apex is the only part seized upon, the rest of the long remaining free. The apex is proue to suffer in quite group children. When this is the case we may hantily attribute

^{*} See Fibrid Philinis, in Chapter XL, On Philisis Pulsamulis or Pulsamury Communities.

the condition to tuheroular deposit, though this form of preumonia would not necessarily seem to be more fatal in this part than in the inferior portion of the lungs. Still we are always anxious when the apex is the chosen seat, for it must be considered a sign of delicate health or exclexia. More or less of bronchitis is usually present in these cases, pienrisy is very common, and there may be some effusion into the pleural sac. When pieumonia is at all severe, the right cavities of the heart are distended, and the heart may be seen beating at the epigustrium; the venous system is full, giving rise to capillary congestion and calargement of the jugular veins. The blood abounds in fibrin, and the "buffy" cost is present.

Symptons.-These are not the same in all cases. In some the complaint sets in slowly, with slight broughitis or estarch for a few days before the long exhibite dulness and the usual signs of pneumonia. In other cases the disease commences more subletly with rigors or convulsions, or there is hendache, vomiting, jain in the chest, and a dry backing cough. Thirst and loss of appetite are usually present, the tongue is covered with a creamy for, through which the enlarged pupilic project, and there is constination. In most instances there is pain in the side, or about the mammary region, extending downwards, which may lead an inexperienced observer to think the pain is alideminal. When the pain takes this course there is generally some pleurier present. It is piercing or stabling, causing the child to ery out if the part is touched, or if there is coughing. The face is maxious and finshed, the nestrils are active at each inspiration, which is short and catching, and the little patient sinks low down in the lod. The skin is usually aerid and pungently hot, but it may be perspiring at an early period of the complaint, with no anciloration to the other symptoms, the respiration being equally hurried, and the general distress quite as great. The temperature varies from 103° to 104°, or even more, the latter being a common elevation in children, and when it does not exceed this recovery is the rale. but it should be borns in mind that in cases of free entances action it may never rise high, and yet the disease be extremely severe and dangerous. The significance of the temperature in est be estimated by comparison of the physical signs. In one case which came under my notice, however, with a temperature of 105", the child had severe lung mischief, but recovered notwithstanding. It is seidem that the temperature exceeds this except in twhereniar pneumonia. One or both cheeks are often flushed, or there is a livid dusky patch on them, and the expression is anxious or heavy, and has a yellow or earthy cast. Stuper and heliference are striking symptoms, as the complaint steals on, and the cough is choking and subdued, instead of tearing and painful.

The pulse varies in frequency from 120 to 140. In mild cases it may not exceed 100, even if the avening temperature runs up to 163°, and the respirations are not more than 28 to 30, but in severe cases the pulse will reach 160, or even exceed this, and the respirations be as frequent as 70 or 80 per minute, particularly where both lungs are involved. The pulse is strong and full in sthesic cases at the beginning, but as the disease advances it increases weak, small, and running; in other cases it is irregularly intermittent.

Nothing can usually be gathered from the appearance of the sputa as at first they are scanty, afterwards they are swallowed, unless the child should vomit, when some rusty or sanguineous trethy liquid may be uiped from the mouth, but the symptoms are liable to considerable deviation both as regards the local and general signs."

If the child is young enough to be nourished at the breast, he repeatedly lets the nipple fall from his mouth, because, with a closed mouth, the nestrils do not admit a sufficient quantity of six to the lungs. When the constitutional symptoms have reached the point already described, the lung will give evidence of some change. If examined at the earliest period the respiration may be little altered, but in nearly all the cases I have seen, when the general symptoms have attained any importance, some dainess will be detected over the lung, and there will be heard on auscultation both rhonchus and sibilus. At the lower lobe of the lung,

Dr. Spirre unter that acrie (Iodar, or crospont) personnis is not uncommon in childred. He quotes the experience of Stanta, of Breslau, with 4d cases, and of Jonesea, of Boeley, who gives 186 cases of processuria, specifically stated out to be exacted of which 117 occurred in the first six years of age, and 40 in the next ion years. Four consecution cases given by Dr. Byriso "commerced stablesty with higher temperature and greater disturbance of requirement and circulation than other scate from at shildhood." An abstract temperature for five at eight face subbasity substitute made these cases. On Infantite Presentation read before the British Medical Association at Mancheson, Lugari, 1877.

fine oregitant rhonehus is heard at the end of inspiration, and bronchial or tubular breatling above of a shrill metallic character from commencing emsolidation. The voice or cry reathra the ear distinctly from the thin state of the clust-walls. When the sounds just mentioned have taken place, the movements of the thorax on the affected side are restricted, and at each inspiration the intercestal muscles are drawn in, leaving the spaces depressal. If these physical signs continue (which are commonly heard about the third or fourth day), the small orepitation is exchanged for a coarser kind, or that known as subcrepitant rheadons, the fluid now being more copious in the air-vesicles, which are dilated and enfectived. The true organization of this form of pregmoula is very brief in children, and is soon exchanged for the courser variety. As the disease advances to recovery, the delines on permason diminishes, and the organization becomes moist and bubbling, whilst the respiration is softer and loss frequent. There is in this respect a great difference in cases, the dulness being slow to pass away in some instances, even if it does not become obronic, and the breath-sounds remaining feeble, barsh, or moist for a great length of time-in fact a course crepitation may remain after many weeks, in defiance of every constitutional and local measure.

Posumonia sometimes commences with sweeze voniting, and feverishness entires at the end of two or three days, with pain is the side, cough, headache, and restless sleep, followed by windering, or even delicium at night; the skin is hot and pangent, and the urine high-colored, with deposit of pink lithates; it may nottain a little alloumen from congestion of the kidneys, and there is a dedelency of chlorides. Such a case came under my notice in November, 1876, in a lad, fourteen years of ago. On listening to the clast the long was dull throughout posteriorly, very divinished breath sounds at hose, with recritant rhondons, but with brenchial breathing and bronchopheny above, and in the lateral region of the affected side there was losse moist crepitation as high up as the axilla. The patient lay on his back (which is the usual position in this disease), the pulse was 100, fairly soft and compressible, respirations 28, temperature 103". On the following day (fourth of disease) the pulse and respiration were the same, but the temperature had fallon to 100°. There was a slight sough, and expectoration of a varnish tings. Ten days later (when I sext saw him) he was sitting up, looking well, except pale. On examination the only evidence of the lung attack was a little dulness of the lower lobe, and deficient breath-sounds. The lung had almost entirely returned to its natural condition, and the lateral region presented no moist sounds whatever; the pulse was 80, respirations 20, temperature normal. The case was a mild one, and came sariy under treatment.

Other cases of paramonia begin with delirium in young subjects, and the symptoms are so obscure that diagnosis is difficult
for a day or two;" there is stuper, convulsions, or coma, and the
tongue is brown with sordes, so that we are uncertain whether
the condition is not one of typhoid fever. In adults we may often
most with this, but in children it is not so common, and if the
pyrexin is moderate, and the bowels quiet, we are tolerably certain of the true state of things. When the delirium is flerce and
continuous, and there is much benduche, the symptoms at an

^{*} The nerven symptoms stiending oper possession (renderal possession) in young shiften are well exemplified in the three following cases. In the first case, a child. In your old, was well on Jure 12th, and raises howe first from whool. In the enting she was converted and lost her amon; the following sky there was discriben, think dight mugh, rigid regiralize, and definion. On the 19th, when whatted has the Children's Hospital, andre Dr. Gee, the temperature was 165.20, pulse 1641 repirition 60; there was datases over the right front as for sothe signle-ferri, becauthird waive and pergeration; for either or inspiration. The temperature fell on the 18th to 2002", and on the 20th to 60". Recovered July 5th. In a second case, a scale child, there and a half years old, was in good health on Paly 9th before 5 max, when because inhers, employed of his head, and timed about. In the evening he ministed. On the little he was diversy, and could may six app. On the 12th, when admitted into the Children's Hogeltal, under Dr. Chendle, he was invitable and promute; temperature 1942"; pulse 160; respirations 52; thin het; tempes red, and control with a white he; tight from of the eax doll in few as alphle, and apper half of anilla; regintice work and besufulal. On the 16th he was exemple, delicion, and combanily trying to get our of hely temperature 194". On the 18th there was less delicious, but mentar resplic the the 20th temperature 101°; has respitation over upper fulf of night front of chest to pipele. 25d temperature 98.4°. Secondary proceds defected after the physical signs had eletted up which was considered doe to the absorption of inflammatory products, or allied to reptioneria, as singer were no signs of taboralieds. On the 12th of Sepwe've he was discharged .- Cases of April Passancela, Medical Times and Gazette, Denoter Sch, 1977, p. 380.

early period of the illness are not unlike approaching menlogitis. In those cases of meningitis complicated with pacamonia, broacheportmonia, pericarditis, etc., great difficulties often present themselves in arriving at a correct diagnosis till the characters of our or the other disease prodominate.

Genera.—These are prelispesing and exciting. Among the former are the previous state of health, and the liability to pulmonary disease. Among the latter are exposure to cold in winter and spring, particularly after measles and the cruptive fevers, debility, privation, violent-exercise, congestion from heart or kidney disease, or from tubercular deposit in the long. The exciting causes, too, are exposure to cold when the body is heated, cronpens exudation in the lung, and the deposit of diphtheria. Injury to the chest, or a blow setting up abscess in the walls of the chest, is another ascertained cause.

Farbology.—The epithelial lining is unaltered in eroupous pranmonia. The exudation filling the alveot consists of fibrin and loneocytes, or "exadation colls," which readily undergo fatty degeneration; they are partly thrown off in the spata, or disappear by absorption, which is quite different to what happens in exarrhal parameters. In the first affection the whole lung, or our lobe, is consolidated, whilst in the last-named variety isolated patches (lobules) are affected, surrounded by pulmonary tissue permeable to air.

Terminations.-Pacamonia generally ends in resolution in healthy subjects. A crisis takes place in the form of sweating or diarrhous, or there is an abundant urinary discharge, and forthwith all the symptoms speedily decline. This may be usually locked for at the end of a week, when the pulse and requiration become reduced in frequency, but the crisis may not occur for another five or six days, leaving the child prestrate, this, and pale. In other cases, when convalescence appears to be approaching, a relayee takes place, and the child may die of authyxia or convulsions from a clot of file in blocking up the palmonary artery and obstructing the circulation through the lungs; or it drags on, and at last perishes from exhaustion. In another class of cases the exudation thrown out is never absorbed, but it provokes fever and cough, and ultimately leads to phthosis or obronic meumoria, which is slowly recovered from if the general health can be maintained and proper treatment is employed.

Propassis.—From the liability of young subjects to tubercular disease, preminents is full of peril to the weak and delicate, particularly if the plears or pericurdism has been involved, or there is repat or beart disease. If both lungs are affected, and there is opious accretion (especially if dark or prune-juice in color), the respiration increases in argency, and collapse is to be apprehended. In such cases profuse perspiration breaks out, low muttering delicium sets in, and the child gradually sinks.

The diagnosis of economic pneumonia is to be sought in the tabular breathing, fine crepitation, dulness on percussion, elevated temperature, and rapid respiration. Change from the normal ratiobetween frequency of pulse and frequency of respiration is very marked is this disorder. In any febrile disturbance in young children the temperature is apt to run rapidly high, even in dontition, but then it is of very brief duration compared to premmonia and in bronchitis it is not usually so high, though I have known it reach 105° when the disease has been limited to the brouchi alone, and the pulmosury tissue has escaped. The rhouchi of pneumonia are more sonorous and sounty, and the moist crepitation is not so loose and building as in broughitis. When neute lotar promnonia attacks the upper lote of a lung, it is liable to be mistaken for phthisis. The exudation poured out in these cases, and the dolness and tubular breathing, are just the signs which ensue from tubercular deposit. The local indications are often trifling, however, compared to the febrile disturbance and prostration, and time alone may be capable of clearing up the diagerois. In the case of simple inflammation the local and general symptoms soon pass off, whilst in tubercular cases they gradually become worse, or merge into the chronic form, when the diagnotis is all the more difficult, if not impossible. Physical signs cannot clear up the difficulty, for both in pneumonia and apox consolidation from tuberele there is great dulness, brouchophony, tol breachial respiration, to indicate that the lang-tissue at this port is consolidated. Miliary tubercle may give rise to no signs. whatever, and the disease usually creeps on but slowly, with fever and emariation, cough, and loss of appetite. Tubercle may be present in some other parts of the body, and there may be a histrey of it in the family. The diagnosis from plenrisy is given in the chapter devoted to that subject.

The symptoms of lober paramonic differ from those of lobular

or colorrhol pressurate in the greater dyspaces of the latter affection, the duskiness of the lips, and the pallid and bloated counts-name. There is more restlessness and anxiety, the cough is loose and cheking, and mucoparalent phlegar is often dislodged from the air-passages by a paroxysm of sufficiative cough or comiting. When the child is too young or feeler to expectorate, the sounds over the affected tubes are loose and extensive. The symptoms in this variety come on earlier, and the vital prostration is more marked.

Preumonia may be distinguished from edema of the lungs by the deliness on percussion and the tubular breathing, whilst in the latter affection the spata are frostly and thin, and the complaint occurs as the consequence of long-continued congestion from heart or kidney disease. The cases of pneumonia may be mistaken for typhoid force, and even meningitis, but these have been abuded to in another place."

Treatment of Labor Phenomia.—In the neute congestive stage, if the child is strong enough, and there is much pain in the side, the application of a few leeches, or even renescriton, is not to be neglected. But it is of the greatest importance to be very contious in the assection of cases for this heroic treatment: these will almost invariably be found in country practice, and solden in large towns and cities. No doubt children have been so saved when all other remodies have failed, and the plan is always one to be held

¹ See Chap. VIII. On Typhoid Ferry, and Chap. XLIL On Disease of the Iteria.

[&]quot; "In a healthy child of few years old a rein may be spened in the arm, and here converted third may be allowed to first provided that fainteen by untarrier protection without there being any mosts for as to approbe at that the plan we are adverse; a no energetic. It often happens that the shall fallers believe this quantity of blind him been drawn, while is other value not above one or two concouran he obtained; still, whetever the patient is seen at the commencement of the attack, general depiction in de-trails, even though it should be necessary to follow it up by local bireling; for the immediate effort which it profuses is greater thin that which follows depletion, that the quantity of blood abstracted by it is definite; while, if both the warse and the reals lead attendant enderstood how to minute children, it may be conducted as at to prothem but little excitoment or alarm. If but very lattle blood can be frame from the near, or if us is not solden the case with infants ender two years of again the sepossible to find a vote, depletion must be accomplished by manual disorker, which for resours already stated, it is desirable in apply beneath the scapula. How great source may have been the relief which followed the first bleeding, it is not always personal. and hence the child should be seen again in from uce to eight home; and if the GMP total appear to be retarring with anything of the former severity, deplation must be

is mind, as it frequently saves the lung from organic change and preserves life. Every case, however, must be treated on its own merits, and if suitable diet and rost are observed the patient may be left to nature in many cases. Two or three lesches to the side in athenic cases have relieved pain and rapid breathing, emising the blood to circulate more freely through the lungs, controlling the temperature, and lessoning the violence of the heart's action. This treatment should be reserved to early in the disease.

Tartarated antimony is a most useful drug, and in strong children it may be given advantageously for a short time in small doess, as gr. Ath to 5th, with the solution of aretate of ammedia, or the Bute hydrocyanic acid (Form, 80). The antimous acts best when it does not provoke vomiting, but simply determines to the skin and lowers vascular action. Valuable as antimony undoubtedly is it must be used with great eaution, and watched very curefully, for in young children it soon causes depression and faintness, and if the occurrence of those symptoms is not guarded against, the local signs-increase instead of improving. This again, like bleeding, is only suitable for strong children in the early stage of the disease, and not for those who have been reared in the contaminated atmosphere of large towns. A few drops of antimonial wise, with citrate of potash and the solution of acetate of ammosix or spirit of nitrous other, will keep up a gentle action of the akin and bring relief. Emetics are not indicated in this form of posamonia.

With the tendency to exudation of lymph mercury may be employed, but more sparingly in this than in some other parenthymatons inflammations. When the constitution will bear it, its action as an antiphlogistic may shorten the stage of exudation, and promote and hasten the absorption of the newly effected lymph

repeated, though then local bloodicening is to be preferred to remember in, even in cases in which blooding from the arm, but been reserved to in the first instance. It would know be largerteen that in the child, as well as in the soluli, no subsequent rare can make my for the medicions treatment of the early sings of paccessorie; if the first tensis flow boars be allowed to pass while you are employing inadequate remedies, the line, which at first was meanly congested, will have become solid, and recovery, if it takes place eventually, will be tarriy, and perhaps imperiod. On the other hand, were that at a with the grannest according ameetings appear to be at case out short by low depletion; the stolingst approach being account, and recovery going an assessmant of appears and experiony going an assessmant of the children of the large of the large of the large and Children 1900, 4th edition, p. 221.

before it has had time to become organized, and to set as an irritant to the surrounding healthy textures. Small doses of calcoal with a few grains of James's powder may be sometimes given with advantage (Form, 62). Minim doses of tincture of accusts are also useful from their power in promoting diaphoresis. The artiphogratic effects of acouste are very marked in relieving tension in the pulse, and lowering arterial pressure, but this drug tends to reduce the respiratory movements as well as the temperature, and acts as a solutive on the cardiac circulation. I have never observed any lad effects follow its administration in neutro pyrexia in small and repeated doses, but great benefit where the vascular excitoment has been considerable, and the skin progently hot."

When the physical signs announce that the long is freely soreting, and athenic action is reduced, a grain or two of the carbonate of ammonia may be given, particularly if the pulse is weak or unsteady, and there are signs of collapse, when it may be safely combined with decoction of oak bank, or senega. Whilst the sputa are viscid and the orine turbid, alkalies are indispensable.

A few grains of hydrate of chloral may be of service where depression is to be apprehensed from the want of sleep. We should bear in mind that it lessens the activity of the respiratory centre and enfectles the vascenotor system—a state of things we are most anxious to guard against. Its action is also very manifest on the sirculation, lowering and neakening the action of the heart, by paralyzing its sympathetic ganglia. The combination of belladonna tonds to obviate this. I should never administer it where the pulmonary circulation was much involved, for fear of increaing relaxation in the vessels and further enfecting the action of the heart.

Bromide of potassium is a safer remedy, having a sedative influence on the nervous system, and so inducing sleep, without depressing the heart's action.

In the shape of local applications, nothing equals a warm inseed or jacket positioe. It should be applied over the whole of the affected lung, as hot as can be borne, and changed once in two or

^{*} See the serion of Associte in Chap. XI, On South! Ferrer.

^{1.} The location scale is because shown and family to rouse, from paralysis of the respiratory century but argent dyapers has accommally been shorted, and the has been accorded to differential of the polescency resords, causing as increased affect of blood to be directed sublemity to the large."—Goods to The species, by Dr. Forgelances, 1877, p. 112.

three hours. The fault of poultiess in general is that they are not made large enough to envelop the diseased organ, for the object aimed at is, not only to refieve pain but to draw the blood to the surface, and so to not as a solutive on the inflamed or congested earts beseath. "In long diseases of children, whose chest-walls are very thin, the value of positives has seemed to be much greater than in corresponding affections in adults; and it is not illogical to believe that the difference may be dependent upon the irreguhrity of the chest-walls." When moderately and enutiously used a turpentine stape is very serviceable. A piece of thick household famel should be folded the required size, then wrung out of hot water, and a few drops of turpentine sprinkled over it. This should be laid over the affected part of the lung, and covered with a piece of oiled silk, or a dry fold of linen rag, and kept on for twesty minutes. When it is removed the skin will be found of a bright crytismatous lose, and the cutaneous vessels will be kept dilated for a considerable time.

The diet should be light, and at first without stimulants. After about five days or a week, when the temperature falls (perhaps with crisis of diarrheen or awenting), whoe, eggs, and additional neurishment are needed. In all cases, milk, beef ten, and cooling drinks from the onset, should be given freely. The temperature of the room should be about 60° and well ventilated; the head mised, and the position changed frequently.

In the treatment of the second stage, or that of bepatization, a flying blister, or the application of iodine may be needed, but this will be more fully alluded to when we come to speak of the disease in its chronic form. The perchloride of narrary in small doses, iodide of potassium, and cinchona, are valuable remedies in their turn. The ammonio-chrate of iron, or the syrup of the iodide, are both useful remedies, particularly if the child is attentic.

In the third stage, carbonate of ammonia, brandy, quinine, and the mineral acids may be required, followed by cod-liver oil and change of air.

Catarrial Parasonia (scale labular paramonia, epithelial paramonia), Branchopmentatoria.—In this variety distinct and separate labules are affected. The inflammation extends along the smaller bronchial tubes to the air-vesicles, or it originates in collapsed.

^{*} Wood on Thempentin, 1876, p. 558.

lobules, which are firm and red. On section they are smooth and give exit to a bloody fluid. It is very common in whooping-cough, mensles, and diphtheria, but it may arise apart from these diseases in consequence of debility and an impure atmosphere. Cold and changes of weather appear to be the most common causes, and nav exhausting disease which has kept the child for a long time in the recumbent posture is capable of originating this mixed disorder. Children who are delicate from birth and have bronchitis are anijeet to it. I have met with children of fifteen months old with symptoms of wasting and marasuma who get broughitis. The wheezing extends down the brought, and involves the smaller brouchial tulies of one lung, increasing the frequency and argency of the respiration, and by retarding the eleculation through the lower portion of the lung leads to dulases and consolidation of it. The lips become blue, and the skin breaks out into a cold clausur perspiration. The temperature may reach 104° or 105°, but it is not maintained at this height, the pulse 200, small, thrilling, and collapsing, and the respirations 60 or even 100 per minute. The child is extremely restless, turning about and hiding the hall of the eye beneath the upper syelid. The duloses may creep upwards above the spine of the sengula, and tubular breathing be detected below the claviole on the same side. There is phlega, which cannot be dislodged, and the child cries out when he coughs, and only gets suatches of sleep. Soon the lung is dull throughout, and the alse man are active; large and loose crepitation succeed, the respiration becomes ratting, and the child may die in a convulsion, or pass into come and sink. In other cases the crepitation which has been heard during the pure broughitie stage is succeeded in a day to two by tubular broathing, harsh and dry; the dulness increases, and becomes apparent in front us well as behind.

Lobular preumonia, when it is at all severe, is a frequent outcome of bronchitis, indeed the two conditions constantly occur together, but they must be recognized as separate and distinct discusses, having a different clinical and pathological importance. "Lobular preumonia is always a secondary discuse, either to those specific disorders which are accompanied by broughitis almost as one of their elements (in which rank measles and whooping-cough stand obviously first), or to bronchitis of a primary kind. So far an excelul post-moreom observation permits a generalization to be made, the course of the disease is invariably through the occurrence of collapse. After a lobule has become emptied of air, and after more or less of the bronelital contents have been forced by inspiratory action into the alveoli, the lobule itself passes into a state of active congestion, and then of hepatization, and by degrees the test of inflation gives only a partial result, and eventually so air can he forced into the lobule. The microscope shows in the earlier periods of this cousolidation the parenchyma of the lung unchanged. but the alveoli stuffed with cells and their epithelium occasionally endergoing some fatty change. The next anatomical change is the coalescence of these collapsed and inflamed lobules into larger masses, which frequently give rise to consolidation of large portions of the lung, especially of the posterior surface. In these, next, a softening change goes on, and the centre of the lobule. loss the dull-brown color of the rest, and becomes gray and dif-Beent, the liquid part having all the characters of pus. Or another process may be set up in the occluded boule, and a cheesy matter he formed, which to the microscope presents various fatty elements and nuclei. This occurs at a later stage of the disease in unbealthy children, in whom, however, miliary tubercle need not exist."1

Pathology.—Unlike the droupous form of pasumonia we have just considered there is no fibrinous exudation, but a cell proliferation which distends the alveoli at the termination of the
smallest brought. These cells are derived from the epithelial
timing of the alveoli where they remain, and as they cannot by
readily discharged by expectoration, they accumulate, cause local
irritation, and form into masses, which undergo retrogressive
changes. Hence the inflammation may lead to abscesses in the
large or to enseous degeneration (arrefulous passensis), or to
tulerendesis, and that terrible scate form of phthisis known as
"guiliping concemption." In some protracted cases the discuse
may terminate in chronic pacumonia.

Protocot.—In this variety lowering measures must be discarded. Ipecacuanha wine in a saline mixture, and carbonate of sumenia, senega, and tolu, are the remedies to be depended upon (Form. 61, 65, 66). When there is an accumulation of phlegm in the sir-tubes an emetic at night to dislodge it will relieve the breathing and insure rest. Some of the best effects have followed the use of mild emetics at bedtime in these and other similar

^{*} Lettomina Lectures—On the Diagnosis and Mongresset of Long Discusses in Children, by George Rechants, M.D., F.E.C.P., The Louves, Feb. 8th, 1868, p. 215.

cases, as broughitis or whooping-cough, where the broughial takes are leaded with mucus. I have not observed any had effects follow the use of a teaspoonful of specacuanha wine, followed by a little warm seator, till somiting energy, unless the child is very exhausted. Generally one or two doses will be enough, but if the child is prostrate, and there is lividity of the face and muous membranes, with a feeble pulse and shallow respiration, the iperpensalm failing to excite cough or vomiting will increase the general distress. The bronchial tubes remain loaded with phlegm and muons, and the general discomfort and pain in the short cannot be relieved so long as the mucus remains. In these cases it may be well to combine the instrumenta with a stimulant like the earlienance of autmonia, or a few grains of sulphate of zine, and if its action is delayed, to tickle the fances with a feather, lest even these attempts sometimes fail, and then our only chance is to place the child in as upright a position as possible is beland support the failing circulation by ammonia, spirit of oblareform, wine, and beef ten. When an emetic acts efficiently it excites the action of the respiratory muscles, empties the larger tubes of their tough or fluid contests, and stimulates the smaller. brought to renewed secretion and activity. The dry sounds and hyperienia of the museus membrane diminish and give place to moist crepétation, and resonance on percussion. The expression changes and becomes lively and animated, the duskiness of surface passing off as the blood is better accated, and the child is restored by refreshing sleep.

The carbonate of ammonia is an excellent remedy by lossening the contents of the bronchi, and favoring experioration. I have many times known children expectorate or bring up phlegm by coughing, just in proportion as they have taken the remaily at not. When the temperature is high and the pulse weak and quick, I have seen excellent effects from combining the ammonia with quining and senega.* This encourages expectoration and improves the pulse and appetite. If the tongue is furred, and the spita

-

B. Anim, ourles. v 121- 125 Truck quintie. . 300 Sea, chlorofites, .

thick and tenreious, the ammonia may be given with blearbonato of potash and iperacumbia.* When there is no tendency to acemulation in the brought, and the cough is irritating and the child restless, a few drops of the compound tineture of campbor, or henbane, may be safely added.

As to diet, the child should be fed with milk and lime-water, chicken or veal broth, and a few drops of brandy may be added to the milk three or four times a day. In feeble children of only a year old I have sometimes given a little champagne in potashwater, with excellent results, and I consider that recovery is often due to the rallying effect of the wine.

As regards local applications, warm linseed poultiess, with or without mustard, as we have mentioned under lobur proumonia, will be of most benefit.

Later on, the preparations of iron—the symp of the iodide, the symp of the phosphate (syrup, ferri phosp., B. P.), the chemical field (syrup, ferri phosp, comp.), or the vinum ferri, will be necessary to strengthen the system and improve the quality of the blood. During convalencence cod liver oil or Squire's mult extract will be found serviceable, or they may be combined with great advantage. The latter remedy may be given in milk.

3. Obrosic Lebelez Permeania.—This is a discuss of great interest and importance from its liability to be mistaken for tubersolosis or chronic plathisis. The connective tissue between the
labeles is affected, leaking to induration and consolidation of the
pulmonary tissue. It generally follows broughitis, posumonia,
messles, se diphtheria, or, what is far more common, it crosps on
imidiously in bad states of health, and may prove possistent and
troublesome. I have met with it in feeble children of rickety constitution, and for weeks together could not decide whether the
disease was tubercular or not. In fact, nutil a case of this form
of pneumonia had been for some time under observation, it is impossible to come to a decision. When we are sure that a child has

A littlespoonful every four bours. For children five or six yours old.

enjoyed good health till an attack of broughtle or whomingcough has happened, and then the complaint passes into localized dulness below one clavide or scapula, with or without most copttation and broughout, we are generally correct in assuming that the complaint is of simple origin. The two following cases examplify this condition.

Cleanic labelar paramonia, simulating interculois; receivery.

Case 1.—V. B——, set. 94, was admitted into the Samaritan Hospital, under my care, on March 25th, 1875. He was a pale, thin, emaciated boy, with light hair and gray eyes, and had been alling in health, more or less, for five years. There was no history of an acute attack. Had had both whooping-cough and measles, his mother dated his delicary to an attack of quinty three years

previously.

On examination there was a general fiattening of the thorax below the clavicle, especially on the left side, to the inner aspect of the corresponding nipple, and this was in a great measure the to imperfect development of the left half of the thorax. He cond take a full inspiration, at the termination of which was a croing, dry, bronchial sound, not heard on the right side. The percusionnote was good in front, but nowhere clear behind; the respiration was harsh and irregular, and there was distinct bronchophony, but no moist sound; the pulse was variable, the least fatigue or excitement at once accelerating it, and I have felt it one day as low as 72, and another as high as 112; the respirations were tranquil, and did not exceed 20 per minute, the morning and evening tenperature 99.2°. He was ordered a diet of milk, eggs, and heef bea; a mixture of hydrochloric soid and quining; diluted tineture of iodine (one in seven) to be painted under the left collar-hone night and morning

In May he was much better, and in June he had gained in fiesh and weight, and his general health was most satisfactory. Temperature normal; pulse 72, respirations 20. The physical signs still indicated some remaining dulness and bronchophony between

the scapula. He was discharged well on June 23d.

Rendmined February 17th, 1876 —Some time after leaving the horpital be seemed to be in perfect health, but latterly he had lost much flesh and strength. The wasting was need apparent about the temples, in the arms and legs, and in the shrunker hands, the sternum and scapular region. He looked like a child in the last stage of phthisis. The chest was clear on percusalon, and expansion was everywhere good, the inspiration was rather short and harsh, but there was no dulness, and the vocal sibration was slight. As the expiratory note was not caught at all, its suppression was probably due to nercousness. In the right supra-scapular space, inspiration was short and rather hareh, but there was neither dulness nor vocal vibration. Immediately below the spine of the scapula, and over the centre of the lone, small cropitant rhombus was most distinct, which disappeared between the inner bonler of the scapula and the spine; over the middle lobe of the lung there were course, loose, and moist habiling rhouthi (suspected softening of middle lolu), and dulness was very marked from this point downwards. There was no bronclophony, the complete absence of which I could not explain, but on inspiration the air seemed to be entering some small cavity, the thin sternal walls only intercening between it and the car, when applied to the chest-wall. There was some consolidation of the lung. In the middle and lower lobes of the right side there was heard crepitant rhonchus, precisely resembling the small crepitint monches of pneumonia; over this the percussion-note was rescunt. The urine was turbid, slightly alkaline, and rather highcolored, with a sp. gr. 1024; on brilling, flakes like albumen Boated. fredr in the specimen, which immediately disappeared with efferreserves (phosphates) on the addition of nitric acid. The pulse was 94, and of good calibre; the respirations 20; the morning termpenture was 29.4°, the eroning 100°. The variation in breathing was very noticeable here-one minute only breatling twenty times, and another as many as twelve times in the quarter of a minute, just as we see in some cases of tubercular meningitis, and gradual death from exhaustion." He was never flushed, and there was no smeating. He was ordered quinine, phosphoric acid, and codliver oil.

254.-The urine was unchanged-be was ordered port wine.

24th—There was more loose crackling in the lung, which appeired to be breaking down, as gurgling and pectoriloops were distinct, and when he whispered the sound travelled up the stethotrope distinctly.

March 9th - During the list few days no broachophony or gurgling was to be heard.

^{*} See Chap. XLII, On Disease of the Brain.

24th.—He had gained flesh and looked better, and although his appetite was good his cough was still troublesome. The change in the physical signs of the long was very remarkable; the note was clear throughout the surface of the right long, there was so trace of brouchophony or moist sound of any kind, except a little dry crackle; all the characteristic signs of breaking-down of long-texture on the 24th olt, had disappeared. The only sound now was prelonged expiration and diminished expansion on this side. It is possible that the cause of this was due to some "Jobsfer previousles" of a chronic character pressing on the tubes, and that consolidation of long-tiesro was set up.

April 21st.—The only change now detectable was that the requiratory normal was weaker over the affected side than the left, every trace of crackling and consolidation having disappeared. He was ordered the ammonio-citrate of iron in five-grain doses twice a day and to leave the hospital. A year later (April, 1877) by

was in perfect health.

Case 2.—This case presented considerable interest, and when sent to me an abscess communicated with the left lung and pleura.

B. M ..., et. 3, a fair and very intelligent child, was admitted into the Samaritan Hospital, under my care, on December 22d, 1876. The mother stated that the child had been siling with broughitis and cough ever since the previous September, and had not enjoyed a day's health since. There was no history of an acute illness; on the other hand, the symptoms were gradual, and at no time marked by fover or inability to leave her bed. On examination there was a prominent and circumscribed swelling on the left side, over the lower riles, about two inches below the nipple. On auscultation there was considerable dulness and imperfect expension below the left clavicle; the voice was bronchophoule and the respiration harsh and broughial. The heart's sounds were distinctly heard throughout the thorax. Posteriorly the dulness extended downwards to the middle of the scapula, and the note was not at all clear below this; the respiration was day and hursle. There sas scarcely any cough to speak of, and the temperature was sorrest, but the pulse was 160, small and weak; the respirations 56, sbott and exiching; the bowels regular and the urine free and clear. A poultice was ordered to the swelling, and a grain of carbonate

of ammonia in tincture of cinchons every four hours." The dietconstant of heef tex, milk, and two rggs daily, beaten up with sherry. On the 24th the abscess was opened and a small quantity of laudable pur escaped; the child had slept tranquilly, without cough, but the pulse was very weak and small. On the 25th the temperature was 98°, pulse 128, respiration 48. The abscess had discharged a large quantity of matter in the night, and this had gives her ease; she sat up in bed and was aware of all that went on around her, but she was prevish and fretful, and boked very pallful and exhausted. The upper third of the left lung was very dull posteriorly, and the breathing dry, shrill, and tubular, but descending downwards these physical signs became less marked. though everywhere they presented a striking contrast to the oppoalte side. On the 28th the pulse was 96, respiration 32; the absees was discharging freely and there was no cough; over the lower lobe on the left side the percussion-note was becoming resonent, and the dry breathing was supplented by course emckling respiration. On January 4th, 1877, the respiration was cleared under the left clavido, but still showed a marked contrast to the apposite side; posteriorly the duluess was diminished, and in the lower half of the long the moist riles were nearly absent, whilst is the center of the lung the voice was broughophonic. A mixture of iron, carbonate of ammonia, and a very small dose of iodide of potassium was ordered three times a day. † On the 15th the abters reformed, and it was necessary to make a counter-opening. On March 2d the patient had gained a stone in weight since admission under the effect of good diet, coddiver oil, and the syrup of infide of iron. The patient shortly after sickened for measles,

and was consequently detained in hospital till April 13th, when the wound had somethy contrized, and no difference could be discovered in the physical signs of either lung, which presented every sign of health.

Chronic passumonia appears to be sometimes caused by disease of the tracked and broughial glands. Dr. Gee has related some interesting cases." Measles, scarlet fever, pertussis, and chronic cough were the causes of the glandular affection. In one case (aged 8 years 9 needles) a cavity in the broughful glands was found, containing a slough, which opened into the asoplargus and left brosohus; the tracked glands were unlarged and cuseous; the right long was studded with military tubercles. In a second-case (nged 6 years) the bronchial glands at the bifurcation of the tracker were transformed into a cheesy mass; the right brouchus was perforated by an ulcer. There was bactic fever during illness: In a third case (2 years old) at the bifurcation of the trackes there was a sloughing early, and the right brouchus opened into it; the right long was entirely solidified; there was beetic fever throughout the illness. In a fourth case (aged 2) years) the tracked glands compressed the lung, and on section the tumor contained a cavity, the size of a walnut, filled with thick creamy pus. The broughful glands were also cularged;

Eleme of the lange, though rare in children, is of sufficient inportance and frequency to deserve careful consideration. There is no oridence of inflammation in the tissue of the lungs, but it is infiltrated with watery fluid, so that it is firm and inelastic: it contains very little air, scurcely crepitates, and sinks in water. On examination of the lungs after death there may be found an effusion of clear serum into the cavity of the plours, or even a thin layer of lymph, proving that some degree of inflammation has taken place. The longs are of a deep red color. On outting into their substance reddish serum exodes, and as it ascapes the pulmousry tissue becomes crepitant and lighter in color. The nirosils and pulmonary connective tissue contain so much fluid that it interferes with the free entrance of air, and explains the cause of the rapid and difficult respiration. "This is a condition very frequently found in Bright's disease, or where there is a disposition to drope; the lung is found filling the chost and heavy, and on a section

^{*} On the Chronic Programmia which strends Discous of the Trucked and Brenchiel Girads, St. Darth. Hosp. Rep., vol. xiii, p. 68.

being made a quantity of serum drains cat, leaving the fiscasbealthy and firm. It is thus distinguished from the first stage of inflammation, in which the texture is very lacerable."

Cours.-We may attribute this peculiar state in most cases to a passive or mechanical obstacle to the free circulation of the blood, as in pneumenia, valvular disease of the heart, and pressure on the pulmonary wins. "Lasmes taught that pulmousry edena may occur as a primary and idiopathic condition, and that the sufficative orthopusa, which menetimes cuts off children after mentles, arises from such oxlema." + Cases have resulted from anasarea after scarlation, from morbid states of the blood, as in Bright's disease, purpose, and the continued fevers. I have seen two cases which occurred as the consequence of constitutional debility, and a low state of the general health. Both were procoled by slight exterch in subspace form of bemchitis), and no alarm was realized till the respiration became rapid, out of all proportion to the pulmonary state. The condition is one not only associated with debility and relaxation of the vessels and tissues, but the quality of the blood has probably undergone a change similar to what occurs in passive dropsy. It is this see and more eatery than in health, the corposeles and organic matters are iminished, and hence the transmitation of the serous parts through the vessels and capillaries.

The physical signs which indicate this condition are not very characteristic or reliable; there is some dulness on percussion, and sacross of voral fremitus; the respiration is weak and often mixed with rather losse riles and subcrepitant rheachus; "the fine bubling rhouchus, when very liquid and well marked, is the most

characteristic sign."

Trustment.—This will depend upon the cause. If the discuss comes on during the amsuren of scarlet fever, the hot-air bath, and disphereties to act on the skin will be needed to remove renal conjection. Small doses of tartarated antimony and spirit of nitrous other will relieve the dyspacea, whilst a positive may be becausary if the bronchial conjection is sufficient to demand it. But it often happens that asdema of the lungs, coming on gradually in strumous and delicate children, domands a supporting line

By the term tuberoulous we mean a general condition of illhealth, attended with the deposition of tubercle in one or mosorgans of the body. It is a constitutional febrile affection, which is usually associated with inflammatory action in the lungs, broadchial glands, cerebral meninges, and peritoneum. We say somranted, because its percise relation to inflammation, whether as a mere variety or as a concomitant, or a result, is still a great pathelogical question, which we will discuss further on. In childhood It has some special and characteristic symptoms which we do ust observe in later life, and the causes and history have a squarate and distinct character. In well-marked cases of tuberculosis the children are usually good-looking, with prominent veins, long eyslashes, and diluted pupils; the figure is erect and slim, the joints are small and slender, and the shafts of the bone thin and straight; the growth of mind and body is active, and the nervous system is highly impressible; the child is sensitive to reproof or kindness, quick and clever at lessons, and does not exhibit the backwardness which belongs to the phlequatic temperament. Those children are not subject to enlargement of the lymphatic glands, nor have they the thick lips and dull expression of the truly serofaious diathesis. Tuberculosis, then, or the tuberculous curbexis, senities that state of constitution which arises from the presence of tubercles; and by tubercles is meant a species of new matter, or

growth, prone to degeneration and decay. In its crude condition it resembles concrete albumen, and consequently becomes soft and frields, and acquires the consistence and appearance of thick cream, or choose, or pas. But a variety of circumstances will determine the character of the expilation, and it may abound in elements at the time which are not to be detected in it at another. It is deposited upon the surface of the mucous membrane of the nir-rolls, se within the purenchymatous structure of the lungs, where, instead of being absorbed or excreted, as happens in the simple exudatice informations of the healthy, it slowly degenerates by reason of its inherent faulty composition and deficient vitality. This question is discussed further on. Tubereles are the local expression of a depraced constitutional state, and most likely represent enfectfed nutritive energy. When few in number they seen sionally become hard and indurated, and do not interfere with the organic functions; but when they are numerous they affect the general health, and if deposited in the lungs, cause in most instances an alteration in the physical signs, and lead to softening and suppuration of the tissues in which they are deposited. The gray and yellow varieties are the kinds with which we are familiar. Under the microscope a section of a miliary or recent tubercle shows numerous seucocytes generally included in a network of delicate fibres-the "solescool tissue" seen in glands. In the confre of the tubercle are large multinucleated cells, sometimes called "giraf offs," the processes of which are directly continuous with the reticulum. The easeons tubercle shows cells in all stages of degeneration and disintegration.

Tuberenlar exudation is most commonly met with in children and young adults. It occars in the lymphatic glands, the lungs, and ecrous membranes, and its progress is generally slow and insidious; but, on the other hand, it is sometimes rapidly roused from lateracy into activity, or set up new by some commonginge disorder. There is no attempt at absorption or perfect cell formation, but a tendency to ulceration and disintegration, with a certain train of general symptoms, recognized by failing health and strength, and persistent derangement of the digestive functions.

According to Virchow, although tuberede is the result of the death of healthy or discased tissues, the local process—tuberculosis—also results in the exadation of a material during tuberculous inflammation; such material undergoing a kind of organization, succeeded by its death, and by its breaking and shriveling up into a tuberele. This gradual change is termed tuberculination.* There is much evidence to be addresed in support of that theory which classifies tuberele as a primary formation, like cancer and epithelial and melanotic growths. All the changes that take place are secondary, and without the presence of malautrition it

seems highly probable that no lesion can produce it.?

The conditions, then, under which tuberculosis originates are not procisely known, as low inflamountary products may cause induration or suggestation, and yet the disease may not be developed. It is not known whother the disease is specific or not, or how it is generated within the body. When the sputa of phthisical patients have been given to dogs and poultry, tuberculosis has sprung up; and the same has been the case with cattle fed with tubercular or scrofnlous products. ! Villenia was the first to show, by a series of experiments, that when finely divided masses of gray or yellow tuberele were introduced under the skin of guines-rigs, rabbits, and some other animals, a local form of inflammation cannot, and at the end of two or three weeks military tubercles were discovered in the lungs, and at a later period in the latestines and peritoneum. Villenin, therefore, concluded that it was possible to propagate tuberculosis by ineculation, in the same way that occurs with small-pox and syphilis. Many pathologists have carried out Ville. min's experiments, and they have arrived at precisely the same results; whilst Burdon Samberson and Wilson Fox made the further discovery that miliary granulations arose in some of the chief organs of the body when pus, putrid tissue, and portion of a pretimonic lung were introduced subentaneously. Dr. Burden Sanderson's experiments on the artificial production of tulerde in the lower animals throw much light on the pathology of the affection as it occurs in man. He found that it is most wallily produced in the guinea pig, next in the subbit, and lastly in the dog. "For three reasons," says Dr. Samberson, "the gelecoping is prefemble; (1) because it is also lately free from liability to natural tubercle; (2) because it is little liable to zoute inflammation; and (3) because it can be inoculated with absolute cortainty." An in-

dollosimal dose of the infective scaterial is taken from the discussed. ghad of an intected unimal, and, after being mixed with a little distilled water, is injected into the peritoneum, the plears, or subcutamous areolar rissus. Drs. Sanderson and Wilson Fox, in 1868, produced tubercolosis in the guinex-pig by the insertion of setons and anothbereither products. An abscess followed around the Sorolgu body, and tuberculosis supervened. Professor Colubelm also confirmed these experiments, and produced tuberenlosis traunatically by introducing tarmless foreign bodies into the peritoneum. The result obtained by these researches was to produce ardnies of new growth, having a lymphatic structure, and termed lynghoms by Virchow, Iocame they are comments found in cortain organs of the lymphatic system. Dr. Sanderson proposes the term adenoid, because he says in certain parts of the body there are organs like these growths we are considering which possess a structure identical with the follicles of the lymphatic plands, and that where they exist naturally, as beneath the pleura and peritoseem, there these tubercular nodules or overgrowths are most frommily found. These nodules or tubercles appear in fact to be nothing more than overgrown masses of pre-existing tissue, or anlarged adenoid Indies."

In fact, these pathologists ascertained that simple mechanical invitation set up the same morbid process as the inoculation of the specific products I have alluded to. Thus it seems satisfactorily demonstrated that general tuberculosis may arise from the inoculation of a morbid poison into a wound, or from the absorption of inflammatory products; and although the injection of tubercular matter does appear to induce the disease with greater certainty and otherty, there is no reason whatever to suppose that any specific inoculation is necessary. These carefully conducted experiments

[&]quot;I am quite willing to achomology a close affinity between lymphatic glandalar trailings and talencies, for they affect the same subjects and run a similar course. But these glandalar worldings also have a close presentations on the one hand to so offining tem inflate surface, and on the other to the simple unlargement of the spice and litter securing is leakered. In both these cases there is doubtless happercapt; or hyperpinia, but this may be in the way of constates a greatly affection, without the development of complex those which constitutes a greatly affect of the first shall produce of inflamenties in a linear constitute a growth, then common sebrates plaughes, inhereing and holds are growths, and the welling from expansion of collection must be metalled under the same term; but this surely would exceed as well are particle."—Palamony Communication, by Dec C. J. E. and C. T. Williams, 1871, p. 17.

have had a surprising effect in modifying our views regarding the
prevailing doctrine of tobercle, and, as we shall subsequently see,
they have an important practical bearing. It decides the longdisputed question that low forms of simple or even acute influmation in some subjects may eventuate in tubercular disease,
without any original deposition of tubercle; and in support of
this view I may allude to the circumstance that neglected pictritic
efficient in children is often followed by empyema and occasionally
by tuberculosis. A common cold in delicate children, or those predisposed to the affection, will now and then give rise to it; indeed,
no vascular excitement in such subjects is to be disregarded.

With regard to the history of the above researches it may be stated, that for the last two bumbed years, talercles were considered to be allied to scrofulous lymphatic giands till the time of Bayle, who regarded tubercio as a poruliar product, and the result of a special constitutional disthesis.-- a deposit depending on a morbid state of the blood. Hayle gave the name of taberele to the gray and vellow masses which he found in the lungs. Virtlew proved that yellow caseous matter was not the character of true tubercle, and that it might arise from fatty degeneration, and the presincts of pus, and cancer, and so forth. He called the grey granulation of Bayle the typical form of tuberele, and considered infiltrated tubercle and caseous masses as the consequence of inflammation. Dr. Wilson Fox entertains the view that the execons products arising in the lung in phthisis are due to the destruction of vessels by a new growth in the walls of the sirvesicles, and that the typical gray granulation is not the oily form in which tubercle occurs." Niemeyer considers that phthisis, as a disease, has nothing to do with suborcle, which is only at accidental and secondary product when found in the lung and the result of inspissation of inflammatory products, leading to destructive and ulcorative changes in the lung-times.

Dr. Fox's researches seem to show that the changes found in the lungs, in acute talerculosis in shildren, are the same as those observed in the ordinary forms of phthicis.

According to this authority, the following are the chief appearances found in the lungs of children dying of acute tuberculous

^{*} Trans. Path. Soc., 1872, vol. 2007, p. 297.

Discussion on the Austonical Relations of Palamance Phylinic to Tabards of the Long. Trans. Park Soc., 1973, vol. 5414, p. 201.

"The semi-transparent granulation of Bayle. Opaque white granulations, for the most part soft, but with varying degrees of firmness and difficulty of crashing. Granulations like the semitransparent granulations of Bayle, and also like the soft granularious, but more or less enseous in their centrus. Yellow soft granulations, easily crushed, but not easily removed from the pulmenare tissue, varying in size from that of a poppy seed to a mustard seed, rarely of the size of a bemp-seed, and will more risely of the size of a split pear. Caseous granulations, der, opique, and friable; sometimes with, sometimes without, a gray trues parent zone of induration surrounding them. Groups of granulations, mostly like the semi-opaque, sometimes entirely opaque, rarely semi-transparent; two or three, or four, or more in number, reaching the size of a split yea, or a bean, or even a small walnut, ce hazebast. Indurated pigmented granulations, singly or in groups, like the last described. And lastly, tracts of indefinite extent, one or two or more inches in diameter, irregular in outline, prominent above the surface, granular on section or tearing of the tisse, but passing sometimes insensibly into the so-called gray infiltration. Cavities, from infinitesimal specks to the size of a lazelant or larger. Granulations softening into cavities-wither the softer, the white or the yellow. The semi-transparent granulation in the long is not, as far as I have seen, found softening into a cavity without some intermediate change. Tracts of gray mil-transparent appearance, known as the gray provincial or 'gelatinous pneumonia,' or 'gray infiltration,' or gelatinous infiltration of Lacance; spots also of red pneumonia; in some cases aslema; in some cases injection or punctiform extravasation; in some cases emphysema and collapse; in some cases capillary bromchitis and dilatation of broughi. The point on which I wish especially to insist is, that the gray granulation of Bayle is very scilors found alone. They are sometimes found as isolated structures scattered throughout the whole lung, but this is comparafound alone in two. They either coexisted with cascous, or with the white and the soft, or with the cascous, or with the soft and caseous, or with the indurated, or with the soft, yellow, and mesons, or with the soft and esseons alone; most of these being combined either with red or gray premmonia, or with tracts of caseous infiltration. Those are the forms of the combinations of which I made notes in eleven cases that died under my own observation. The gray granulation of Bayle, the typical taberds of Virchov, does not therefore exist alone in the majority of cases of sente tuberculosis in the lungs of children. It is most conmonly associated with other granulations, which have a different appearance to the naked eye, and also a different anatomical structure; and the latter, in some cases, are the predominant change, so that in some lungs the gray granulation is comparatively care."

Unlike the case of adults, gray granulations and crude miliary granulations frequently exist in children as the only form of takercular deposit. In the adult, M. Louis-discovered miliary tubercles alone in 2 out of 123 cases (L6 per cont.), and gray granulations alone only in 5 more (4 per cent.). In the child, Riffiet and Baether found miliary tubercles without gray granulations in 107 meet out of 265 cases, and gray granulations above in 38 out of the same number of cases. In 102 cases of pathisis in children, Dr. West* found military tubereles alone in the lungs in 20 instances, and gray gravulations alone in 17 more. Another anatomical peculiarity in early life is the great frequency of pellow infiltrated tubercle. It soldon exists alone, but is generally associated with crude yellow tuberele and gray granulations, and sometimes with advanced discuse of the brouchial glands. Rilliot and Barther met with it in 88 out of 265 children, or in 33 per cent of their ciscs.

As to the frequency with which we meet with rubercle in the different organs in the body, Steiner found the intestine involved in a third of all his coses; the most frequent sent being the confiintestine, and the least frequent the large. From 892 dissections made in the Frague Hospital by Drs. Steiner and Neurralow tubercle was found.

The broughial glands were affected in 275 cases, the lungs in 135, and the stomach in 4.* In 312 children in whom Rilliet and Ba-

^{*} Disease of Infancy and Childrent, 1th elities, 1839, p. 448.

^{*} String's Discuss of Children, by Lowers Tot, 1874, p. 228.

then found a deposit of tuberele in one or more of the viscous, the lungs were healthy in 47 cases; whilst in 123 similar instances in the adult, Louis only found one such exception.*

Dr. Wilson Fox mentions 61 cases which he examined for the chief purpose of illustrating the pulmonary manifestations of the disease. All were above ten years of ago, and only 2 below fifteen and two ages not stated. In all the cases but one the lungs were affected, and in this was a combination of tubercular plaurisy with tubercular peritonitis. In 7 cases the data were uncertain; in 3 cases the disease was limited to the lungs; in 7 cases two organs were affected; in 16 cases three organs; in 12 cases four organs; in 9 cases five organs; in 6 cases six organs; in 1 case seven organs.

M. Louis entertained the opinion that when subsrcle appeared in any part of the body it was sure to exist in the lungs also, and that the apices of these organs were the solutest scat of deposit. We now know that this is by no means the universal law, which the proposaler considered he had established, but it hooks good with a few exceptions, and is of cust assistance in diagnosts. I have heard it assorted, and I have also seen it in books, that in every case of tubercular meningitis you will find, on examination after death, ordered of tubercle in the lungs, kidneys, peritoneum, or sphere; but twice I have made a post-morton of this well-developed cerebral affection without finding a trace of the pseuliar exadation in any other organ or tissue of the body.

The sudden manner in which tubercular disease sometimes springs up without any obvious exciting cause, is alarmingly suggestive that an over-excited or ill-nourished organ may initiate the peculiar deposition in the track of the bloodvessels, and there set up decay and destruction, having no inclination to spread and contaminate other organs and tissues. Dr. Pox mentions a case recorded by Herard and Corall, in which the disease was limited to a single lung, and he speaks of three other recorded cases where, in addition to other lesions, one lung was affected, and the other remained free.

It was long held that when tubercle was deposited in the lungs it would somer or later proceed to a fatal issue; but repeated exsulnation goes to prove that it is sensetimes spontaneously arrested,

^{*} Meige and Popper's Disease of Children, 1874, p. 843.

[!] Trunc Path, Sec., 1677, vol. maje, p. 371.

and it has been said that this happens in one-third of the persons affected with tuberculosis. This is confined to no stage or period of the disease; it may be stopped in the early stages when the deposit is small and triffing, and instances are met with where large earlities have heated and electrized. "Nothing is more connou," says the late Dr. Hughes Bennett," "in examining dead hodies than to meet with cretacous and calcarcous concretions at the agrees of the lungs more or less associated with cicatrices. Of 73 bodies, which I examined consecutively some years ago in the Royal Infirmary, I found these levious in 28. Of these, prekerings existed with induration alone in 12; with cretaceous or colongeous concretions, in 16. Since then I have examined many handred lungs at the inspections in the infirmary, and am satisfied that these proportions exist pretty constantly. At the Salpetrière Hospital, in Paris, Roger found them in 51 bodies out of 100; at the Bicetre Hospital, in the same city, Bondet found them in 116. out of 135 bodies." In 1888 a young man who had a young in the apex of the left lung, brought me from time to time portions of calcurcous matter, the size of a yea, which he coughed us with expectoration. He was greatly reduced in fesh and strength, but when I saw him, five years afterwards, he had improved in every respect, and the cavity in the long was apparently contracting. I mut with a similar case in 1874, and the patient was living in 1878, and in health.

The following facts, according to Dr. Benneit, are proof of arrested tubercle:

"1. A form of inducated tubercle is frequently met with, gritty to the feel, which, on being dried, closely resembles cretacous concretions.

"2. These concretions are found exactly in the same situation as tubercular deposits are. Thus they are most common in the lungs, and at their apieces.

"3. When the lung is the sent of tubercular infiltration throughout, whilst recent tuberde occupies the inferior portion, and object tuberde and perhaps caverns the superior, the cretaceous and calcureous concretions will be found at the apex.

"4. A comparison of the opposite lungs will frequently show,

^{*} Desithweite's Retrospect, vol. zivii, 1863, p. 55.

that whilst on one side there is firm encysted tubercle, partly transformed into cretaceous matter, on the other the transformation is perfect, and has occasionally even passed into a substance of stony hardness.

#8. The puckerings found without these concretions exactly resemble those in which they exist. Moreover, whilst puckering with gray indunation may be found at the apex of one lung, a puckering surrounding a concretion may be found in the apex of the other.

"6. The seat of cicatrices admits of the same exceptions as the sent of tubercles, and in about the same proportion. There can be no question, therefore, that these sicutrices and concretions for the most part indicate the arrestment, disintegration, and transformation of pre-existing tubercular exudation into the lungs."

Casses.-Of the causes of taberculosis, and the deposition of talercles in the lungs, the progress of medical science has not yet malded us to speak with any degree of certainty; and the same may be said of that variety of disease classified under the comprebenive term scrofula, with its external aboosses and distiguring sternilous. It is very difficult to assign the correct value to benefitary transmission from parent to offspring, regarded as a pealispeaking cames of tuberculosis, because a large propertion of the population is subject to auti-hygicule conditions, which call the insense into existence. The lives of so many young persons are passed in these days of hard toil under such unhealthy conditions that it is readily acquired. What is gleaned from purents respecting their family history is frequently vague and deceptive. Some will tell you that consumption is not known among them, when closer investigation satisfies us that some member of it has suffered from hip-joint disease, open abscesses in the neck, and even fatal affections of the head which must have had a strumous stigin. Instances of hereditary transmission are constantly seen is the emeriated frame of the infant whose consumptive mother largly survives the birtle. When the child dies, the lungs and other internal organs are so studded with tubercles that little hould can be entertained that the disease originated at the earliest period of utero-gestation. It may be laid down as a law, having Sex exceptions, that the union of healthy parents results in the birth of healthy children, and that they grow up to be strong and rigorous; but that when one parent is tuberculous and the other healthy, tuberculosis is upt to show itself in the offspring. As the children one after another reach a certain age they begin to lose flesh and strongth, and at last die with all the symptoms of pulmonary phthisis, or tubercular disease in some other organ. The best explanation for this large class of cases, which we observe where the victims have been carefully shielded from exhausing or depresing influences, is to be found in a blood dyscrasia or some changes in the vessels or tissues.

Youth is one of the most fertile predisposing causes of tuberealosis, the blood in childhood having a great susceptibility to undergo those changes which constitute the peculiar pathological transformation. We can only conjecture what the specific change is; but we do know that in early life the blood is deficient in solid constituents, and in blood-corpuscles. As children grow to maturity, and life advances, the quality of the circulating fluid is enriched, the tendency to tubercular change becomes less and less, and the power of arrest or climination is acquired if the constitutional strength can be maintained. It may be that the diminished number of red corpuscles in chlorosis and arcumin is one reason of their fatal termination being frequently accompanied by the deposit of tubercle and the gradual development of pitthisis.

The effect of intermarriages has been well pointed out by Sir William Jenner. "That tuberculosis is transmitted from parent to child is one of the best established facts in medicine. The extrems frequency of tubercular diseases in some circumscribed country districts is, in part at least, explicable by the frequency of intermarriage amongst persons living in such districts; sail conversely, the exception of particular circumscribed districts from tubercular disease is due to the same cause. In our case, from some special circumstance, tuberculosis has been introduced into the district, and then spread in it from the cause I have mentioned, i. e., intermarrying; in the other case, the freedom from the disease of the district, at any given time, is the cause of its continued freedom. Intermarriage of the inhabitants, the disease being absent, prevents its introduction."

Where hereditary transmission is so strong (and that it is so daily experience affords the most conclusive evidence), the germ of the discuss either lies in a latent state, or is actively transmitted by the parent. Rilliet and Barther furnish some interesting facts

^{*} Address before the Epidemiological Society of Lordon, 1806.

to the effect that, "of 26 children whose fathers were tuberculous, or probably so, 22 died tuberculous, and 4 non-tuberculous; of 32 children whose mothers died tuberculous, or probably so, 22 died tuberculous, and 10 non-tuberculous; of 6 children whose fathers and mothers died tuberculous, 4 died tuberculous and 2 non-tuberculous. There were 46 cases, or about 1 in 7, in which the hereditary influence more or less prevailed, and 11 in which it was the sole probable cause." There are many points of extreme interest on this part of the subject, such as the relative frequency of its transmission by the two sexes, and the manner in which this takes piace.

Children brought up by hand, and weamed too soon, or neglected by the mother, are very liable to the disease. A case is related by Meigs and Peppert of a healthy woman, who had several vigorous children whom she had nursed. She gave birth to one which she could not nurse, and this child, after pining for many mouths, died

of tubercular meningitis,

Pad or insufficient food, leading to prolonged indigestion and diarrhom, exert a powerful influence in the production of tubercle. Artificial foods of all kinds, when too exclusively relied on, way awaken the disease; and defective nutrition and mal-assimilation, however brought about, are common causes of tuberculosis in those who are not even predisposed to the affection. The cruptive fevers and whooping-cough frequently act as a starting-point, the disease having an admitted tendency to spring up after these soute affections. The continuance of febrile action is liable to after and deteriorate the quality of the blood, and to render the system liable to titlercular deposit. If we look back in memory only to our experience of the number of children who have exhibited symptrans of tuberculosis, as the consequence of febrile disorders, we are in a great measure driven to embrace the doctrine that such discases as whoreging cough and measles not unfrequently originate the disease in constitutions not hereditarily tainted,

In those cases in which pneumonia and bronchitis are associated with tuberculosis, it is a disputed question whether the inflammation is a secondary affection, or whether it has been the essential and true cause. Both views have some show of reasoning, and I shall therefore consider the subject at some length. We may

^{*} Ancell, on Tubercubnia, 1862, p. 377.

¹ Diseases of Children, p. 842.

repeatedly witness children whose general health fails for much together, when the physical signs afforded by assemblation and percussion reveal no evidence of abnormal change in the palmonary organs. The disease may advance considerably before they afford any proof of alteration, and there may be extensive inhercular deposit, which is assembled.

The plasma exuded in states of acute inflammation resembles so shoely that which is proved out in low forms of disease, happening to eacheetic and tubercular subjects, as to be almost identical. In the former case, the essential difference consists in its rital endowments, or capacity for higher organization; whereas in the latter it has no power to advance in this direction, and the exulation remains much in the same condition as when it was first secreted. The physical and general signs, too, between a case of chronic pneumonia in a weakly person and tubercular infiltration, are so closely allied that, notwithstanding that the history and progress of the two affections may be some guide to diagnosis, they constantly fail to put us in possession of any conclusive stidence. Now, it is worthy of notice, that a general cachexia regulates the anatomical character of all these exudations, and that in the absence of any apparent exciting cause there has still been a factor in operation, which deals a fatal blow to the doctrine of spontaneous origin. The children of consumptive parents may bear characteristic proofs of the disease, but all do not die of phthisis some may attain to a ripe old age, and others as they reach naturity drop off one by one. Every child bears traces of the constitutional diathesis in the delicacy of form, accelerated circulation, and general appearance; but some have escaped the circumstances which call tuberculosis into action. The different functions of the body are languably carried on, and enough nourishment is appropriated for the maintenance of life; or from some uniforescen causes (ever ready to come into operation) a period arrives when an inflammatory affection of the lungs, or some other part, springs up. Through perversal nutrition, the exadation or effusion of congulable lymph takes place, and local disease is initiated. Here is an argument suggesting the probability of a new power or agent suddenly altering the nutrition of an organ; but it may be contended, with equal force of reasoning, that the unudation was there simularing and undiscovered, and only required the stimulus of external causes to roose it into action. I think

strong arguments may be adduced on either side. It is evident that the earliest signs of inflammation should be looked for in those persons who manifest the tubercular cachexin; and it will, I think, accord with the experience of most physicians when I add that there is a susceptibility to irritation and congestion of the pulmously organs from trivial causes in these cases, similar to what occurs in the different textures of the body, when the blood is contaminated by the detention of noxious elements, which the impaired or damaged secretory organs are unable to eliminate from the system.

"Catching cold " is so constantly assigned as the starting-point of notive pulmonary disease, that we cannot escape from the conclusion that it is no mean factor in the development of tuberculesis. There is a case recorded by Dr. Hermann Weber" of a boy, ten years of age, the son of healthy parents, who had an ordinary sore throat, in August, 1871. This was followed about the twelfth day by pain in the right side of the throat, extending to the ear, and causing deafness; the tympanic membrane became yellowish and prominent, and Dr. Weber suggested that it should be perforated, and if the advice had been carried out it might have saved the glifth's life. In November, 1871, he logan to cough, and was sick and feverish; the poles was 139, and the temperature 103". The chief symptoms were bendache, sleeplessness, constitution, and dry cough; crepitant rhough) were beard, but no dulness. There was deafness, but no discharge from the car, and the prine was nonalluminous. There were two temperature elevations every day between 103" and 105", and two depressions to between 98" and 100°, and the pulse varied from \$5 to 160 in the minute. The boy died, November 26th, and during the last few hours of life the temperature reso from 101.5" to 106". On a post-mortem examitation gray miliary tubercles were discovered in the pleam, pericardium, liver, and meninges of the beain. The right temporal bose and internal var were normal, but the tympanic cavity was filled with soft caseous matter.

Indifferent health may be present in a large number of cases for years, and the patient may remain free from any actual disease; but when exposure has led to cough and felicibe symptoms, then easie the usual signs of broughlits, accompanied with expectoration. No dalness is to be detected below the clavides at first, or

^{*} Climical Transactions, vol. vol., 1873, p. 153.

above the spine of the scapula; but, at a later period, this signifcant sign is added to the rest, and we are irresistibly led to believe that we are dealing with a case of pulmonary phthisis, originating In catarris. In many young persons, when the chest yields a clear note on percussion, and there is broughitts affecting the smaller as mell as the larger tubes, the lungs are found studded with miliary tubereles after death. Death has been so rapid in many instances that the development of these granulations must have preceded the last inflammatory attack to have reached such a mature stage. The diminution of resonance (often not to be detected) does not become apparent in these cases till the broughitis has existed for some considerable length of time. I do not think that this riest altogether invalidates the doctrine that the tubercles may not bare initiated the broughitis. The same causes originate varied affections, modified by susceptibility and constitution, though not following the same order.

In the progress of ordinary phthisis, which continues for years, each fresh attack of tubercular deposit is preceded by brouchitis. It is of common occurrence to meet with children who have datters under one clavicle, barsh or feeble respiration, defective expansion, and prolonged expiration. Such a patient takes celd or gets wet through, and then the dulaces on percussion is increased, and the inflammatory process leads to a further deposit of tubercie.

When tubercle is being deposited in the lung, broughtts is one of the most common attendant symptoms in young subjects. If the broughttis is persistent, and does not yield as readily as the uncomplicated affection, it excites suspicion of tuberculosis; when tubercle is disseminated equally through the pulmonary organs, the sign of consolidation is sometimes wanting, and this is apt to lead as astray. In a deprayed state of bentth, the formation of tubercle takes place rapidly or slowly, and general erepitation may be detected throughout the chest; but there may be midder deleness nor prolonged expiration. There is but little cough, and if the subject is young the expectoration is smallowed. As the disease advances these last symptoms become more developed, hence tysis occurs, the lips become livid, the extremities cold, and deficient may supervene. These are, of course, rapid cases, and strictly bear the name of neutra phthisis."

Febrile symptoms are significant, and when the attacks are

severe or frequent they will generally be found dependent on the rapid formation of Inbercles. But persistent feverish symptoms are sometimes met with in young children when there are no signs of a local character in the chest-no cough, no wheezing-and yet after death the lungs are found to contain talercles: "I attended a little boy," says Dr. James Russell, of the Birmingham General Hospital, "aged six, with one of the most experienced surgeons of this town. His illness lasted for eight works; my attendance comprised the last week only. His sole symptom was persistent fererish reaction, though with sourcely any delirium; the one single symptom of a local character was constant rapidity of lessthing. The child's chest was scarched over and over again, both by my colleague and by myself, for any indication of discuse, but to the very last percussion was normal; not even a wheeze could be discovered; and there was entire absence of cough and expectoration. Death was rather sudden, I suspect, from fainting. On examination, both lungs were positively filled with subercles."* No mention is made of the temperature, but the feverish reaction. and rapid breathing were very significant. If the half of one lung is obstructed in its functions by the rapid development of tubercles, they must occasion serious mischief by diminishing the power of the respiratory apparatus. In some cases where the production of tubercles is rapid and general, a state of tubercular asplyxin takes place, attended with emburrassed breathing boolering on suffication, without suppuration in the lung or the usual symptoms of phthisis.

What is the pathology of such a frequent case as this? A young person takes cold in winter and is seized with cough—spitting and dysparsa. During the cold weather he is tormented with his nilement, and cannot lose it till the warm weather returns. The patient appears in good health, and has not lost flesh or strength; he relishes and digests his food, and there is neither sweating nor diarrhers. He is well in the summer, but every winter has a return of the symptoms, and each succeeding attack is more troublement to shake off than the one that has preceded it. By and by the disease does not subside in the summer, and general and physical algres are added, which prove the serious nature of the affection; he sow slowly begins to lose flesh and strength, and the expecta-

^{*} Braithwaite, On Ferrer and Promisition or early agent of Phythinis, vol. 145, p. 70, 1861.

ration becomes thicker and purulent; dulness is detected in one or both a jects of the lungs, followed by softening, and a fatal termination. So much for bronchitis as a cause.

I am not sure that the means employed to reduce pneumonia in some constitutions may not prostrate the vital powers and lead to degeneration of the offused lymph, which otherwise neight become organized and east off in the healthy progress of the disease. No problem in medical practice demands more consideration for the solution than that which requires us quickly to determine at the bulside, how far we may safely venture with antiphlogistic remsdies in acuto disease. If artive inflammation long assalla vital organs like the lungs, and is timidly dealt with, the effused products after a while resist absorption and become irritating; and if the morrares employed are too vigorous, then the general strength may either fail at once or decline more guadually. But a deadtr disorder may grow out of the attack. Base as it is for tabarenlization of the lung to succeed pneumonia, recent investigation have shown how numerous are the sources of blood contamination. and from what slight irritation it may arise, so that we cannot dismiss the danger from our minds where a large extent of long is involved in inflammation, even if no predisposition exists

Symptons.-It is a distinguishing feature of tuberculods in childhood that several organs may be affected at one and the same time, the lungs, the liver, the pleurse, the spleen, kidneys, and peritoneum, when special symptoms common to disturbance in any of these organs become developed. The general symptoms, however, may be present for an indefinite period without our being able to trace any local lesion, and when this is so we shall presently see that the elevation of temperature is the only reliable ground for diagnosis. The symptoms will vary according to the seat of the inhercular leaden. Among the earliest I have noticed is pain in the stomach, the child being frequently brought under our notice by his parents for this solitary symptom, when the suces peneral and common features of the disease, as loss of flesh, thirst, and evening paroxysms of heat, have not yet indicated its approach-I have particularly noticed this symptom of gastric pain, and occasionally vemitting, even in these exceptional instances where I have had reason to think considerabe care has been hestowed on diet and regimen. For weeks together I have known this symptom continue, and while it lasts digestion is interfered with, the callfree have a pinched and exhausted look, and they lose flesh quickly. It demands attention and care, for it may be the evidence of mischief springing up in the abdonum or peritoneum when the lungs are free from any inditration of tuberele.

Among other common symptoms is a enpricious and irregular appetite, sometimes amounting to hunger, while at other times fool is so disliked that the weak stomach can rotain it only for a short time. When the meal lies too long undigested in the stomach it ereates flatulence, pain, acid emetations, and diarrhosa. The motions vary in color and consistence, sometimes being deficient in bile and costive or loose; at other times they are dark, or have a glairy appearance resembling the white of an egg; the arine is aid and turbid on standing, throwing down pink or even white lithatm; the tongue is glazed or furred at the dorsum, or it is of a bright red at the tip and edges, the papille being prominent. When the appetite is easeleious there is a dislike for any fatty kind of food, thirst is commonly present, and the pulse is habitually quick and weak. If the local symptoms remain obstinate, a state of heetie fever is established, and under emericion, high semperature, and disphoresis, the patient gradually dies with the local determination of tuberele to some special organ, as the longs, brain, or peritoneum.

Tongersture.-Wherever the deposition of tuberels is taking pitce, the temperature gradually increases in elevation, and the destructive changes in the lung continue. Of (wenty-four cases recreded by Dr. Ringer, in which tuberele was being deposited, in twenty-one there was a continued elevation of the temperature of the body, and in these twenty-one cases the deposition of subsecle was proved, during life, by increase of physical signs, or after death by the post-mortem appearances." The temperature, according to some observers, has been noticed not to exceed 99° in some cases of sente tuberenlosis, and that in the evening, when the maximum temperature is usually attained. It must be admitted that these cases are exceptional; and here I would give my own experience, that the temperature has been persistently higher in the evening that in the morning. But when this process of deposition has omed, the lung becomes tough and puckered, and the cavities fined with fibrous walls, whilst the temperature falls to the normal

^{*} Shittle Temperature of the Body as a means of Diagnosis in Phitinia and Taber-value. Walton and Maberly. 1963, p. 3.

point. So it seems evident that when the granulations have under gone this change, or have become quiescent and coased to irritate, tuberculosis is curable. These cases are not unusual. Broachitle, which is so commonly associated with softening of tubercie, and recognized by rhoughus and moist sounds, is a symptom to be expected and watched for. Here we have a rise of temperature proportionate, probably, to the tubercular infiltration and the broachitis set up by it, though there may not be enough to interfere with the proper accusion of the blood, or to excite eough or

dyspnes.

Small deposits of tubercle, when scattered through a consider. able portion of the lung, are not to be detected by physical signs, and we may not suspect such a condition till a disease like presmonia or plearisy sets in. Most of the symptoms of failing health and delissoy in a young person are put down to some change of constitution in the absence of frequent cough and expectoration, but the mischief has long been resident in the lungs, and the inflammatory attack only was wanting to rouse the graver evil. Some years ago I met with a young person who caught cold, and got an attack of pacumonia. There were frequent dry cough, increased frequency of respiration, brouchial breathing, accelerated palse, wasting, and high temperature, but no expectoration or moist rilles. Percussion was dull and bronchophony was general over the posterior surface of the lungs. The patient apparently recovered, but two years later died with all the symptoms of pulmonary inferculosis. For years she had been delicate, and her family Stared she might die of consumption, but one modeal man after another assured her friends there was no deposit of inherele.

There are many cases of children dying of subscredar mentgitis, in whom tubercle is also met with in the langs and paritoneum, who have exhibited no symptoms of its presence during life, and yet after death it is found so abundantly scattered through these organs, that it becomes a mystery how it was that we did not discover the morbid changes that were going on by some general or physical signs. Even the careful symptoms are sometimes so rapid and unexpected that the source of mischief must have been lying dormant for some considerable time.

When, moreover, it happens in tuberculosis that the weight of the body is kept up (and this is not manual if the appetite is good, and there is no exhausting distribut going on), we are the more driven to rely on a continued elevation of temperature as the only sure point of diagnosis in doubtful cases. For a considerable time the temperature may continue high and the weight of the body remain undiminished, as in many cases of ordinary and advanced phthisis the patients retain their weight when sating well and taking cod-liver oil. But this symptom would not justify as in concluding that the disease was arrested, unless physical signs were present also, and showed improvement. It will be acknowledged that, when patients with considerable long disease are progressing most satisfactorily, they are liable at any moment to a relapse with the complications of profine expectoration or hemophysis. In these cases, if we watch the physical symptoms, we could startedly be unprepared for the changes.

The temperature in tuberculosis is subject to so much variation that a large field of observation is required to draw any practical conclusions from it, and cases require careful and diligent watching. When, in any given case of illness in a young person, the temperature is daily devated for a considerable period, and the outlined fevers can be excluded, we may suspect tuberculosis, even if the general symptoms scarcely point to the possibility of this condition. We must be sure that the thermometer is correctly registered before it is placed in the axilla, and that the arm is kept well against the side for ten minutes or a quarter of an hom." The temperature is said to be so slightly altered in some cases that it scarcely exceeds the normal standard, but my experience induces me to think that it never remains so if tubercle is being deposited. Soon the evening temperature is slightly elevated, and later on, in some instances, there is a rise both morning and evening. At midday, or about 5 p.m., we often observe a regular and well-marked rise, varying according to the activity of the discuso.

Dr. Wilson Fox† says that "Lebert figurd in 22 cases the mean evening temperature of neute subcreakesis was as follows: in 2 not exceeding 100.4"; in 8, including those last mentioned, not exceeding 102.2"; in 9, more than 105.4"; in 4, from 106.4" to 104"; in

In the case of young and fractions shillden, the themsensier may be inserted into the section, and one nations will be long enough for it to remain there.

¹ On the Temperature, Police, and Respiration in Phthisis and Acres Tuberculings of the Lange, Med-Chir. Trans., vol. 1ci, p. 200.

1, from 194° to 105,5°," Dr. Fox found that a temperature of 194° was not exceeded by 82.5 per cent, in acute tuberculosis, and by S5 per cent, in acute phthisis. Temperatures exceeding 195°, with two exceptions (scente rheumatism and phthisis), are found exclusively in acute tuberculosis. Both Wünderlich and Lobert record cases of hyperpyrexial temperature before death. The latter mentions one case where it rose to between 197° and 198°, and, as we have noticed (p. 485), the temperature reached 195° shortly before death in Dr. Weber's case.

The more I have thought and pondered over the fluctuations of temperature in disease, the more I have doubted the possibility of constructing any classification from which to draw any accurate conclusions. Diseasos like tuberculosis and phthisis, which are usually protracted and tedious, are those generally selected for experiment; but even these give such varying results that nothing absolutely definite or uniform can be gathered from them? Patients must live under precisely the same circumstances if deductions are to be of any practical value; the hygicale coolitions must be alike, the age and constitutional tendencies must he weighed and balanced; the state of the lungs must correspond, the disease being either active or quiescent, and the treatment must be the same. When tubercle is forming, the temperature may rise to 1050 or more. Dr. Theodore Williams has recorded a case of phthicis in the "active third stage," in which the maximum temperature was 104.6%, and the nóminum as low as 93.4% f There is often a rise after 2 r.m., or, as is frequently the case, about 5 s.st. At the latter time it not unfrequently rises to the highest point in tuberculosis. It is possible that tubercle may form and the disease advance without any rise of temperature, which is perhaps due to exhaustion and collapse. The last writer also mentions a case of phthisis in which active disease was going on, and there were nightsweats and homoptysis, and yet the tenperature was normal throughout I

Scentiag, which so certainly reduces the general strength, is a common feature in cases of phthisis, though it is not seen a news

2 Hot, p. 79.

^{*} If it is the rule to meet with high temperatures to inferrorboin it should not in forgetter that the large may be stadded with tubectles and the temperature forms permitted law.

o On the Temperature in Phylinic Pulsamalis, Med Chie, Trans., vol. Irid, p. 95.

sary feature here. Where the temperature remains persistently high for some time and then begins to decline, sweating is met with. In cases of nervous exhaustion and general weakness it is to be anticipated, so that, though it is not an invariable rule in phthisis or tuberculosis, the debility consequent upon either of these last conditions may produce it independently of elevation in temperature. The aweating that is due to a febrile condition of the holy is generally noticed as the fever declines, and it thus becomes a unitural and efficient means of reducing the lever without the aid of drugs; but when it comes on from sleep or exertion or fisting, it is due to exhaustion. How for these conditions may escalat, viz., fever and debility, is a point we cannot always easily lecide, but, as the case advances, the difficulty is cleared up-Sweating, therefore, is a für less certain indication of tuberculosis than a persistent elevation of temperature; though, where the latter condition exists, too much weight should not be attached to its importance as a significant sign.

Palse.-The pulse is another and more valuable guide than menting. As the temperature rises the pulse usually increases in frequency; but this is not an invariable rule, for the temperature may reach a high point, as 103° or 101°, and yet the pulse remain infrequent, and the respiration quiet. I wm inclined to think that shen the pulse and respiration remain slow, and the temperature greaten rising, the patient is often in a perilous position, and that niere correspondence in the relations are preferable for a hopeful diagnosis, than other the variance is so great. The pulse, there-fers, is no guide in the absence of fever, or the deposition of tabercie. Then, too, when the temperature is falling, debility and exhaustion may send up the pulse, so that this is not an infallible gride-a percent or hysterical temperaturnt will accelerate the circulation, and this may deceive some persons if they are not awars of the condition. The pulse, therefore, as a guide to the finguous of tuberculosis, is of less value than the elevation of temjerature. Dr. Wilson Fox says that an accelerated pulse is not constant in neute taberculization of the lungs. He contends that it may be frequently less than 100, and in some fatal cases below 70 both in the morning and in the evening. When the discuss is progressing or established the pulse is quickened. When it is slow, and accompanied by a low temperature, there is more chance of the disease being arrested or cured. Of the relation between the pulse and the morning and evening temperatures, which is not without scientific interest and practical value. Dr. Fox found in 54 cases that the croning pulse was quicker than the morning in 20 cases; it was slower than the morning in 22 cases; the evening pulse equal to the morning in 12 cases. Of the mean pulses, in 46 cases the evening pulse was slower than the morning in 28 cases; the evening pulse was slower than the morning in 12 cases; the evening pulse was equal to the morning in 6 cases.

The respiration becomes accelerated in proportion to the screenty of the disease, and that in the evening is somewhat in excess of the morning. Sometimes quickness of breathing is the chief but everlooked symptom in armte tulicroulous; and I should attach extreme weight to such a symptom, as I should also to oppression of the cardine region and dyspaces in rheumatic pericarditis before physical signs were present. The respiration, as may be expected, bears a close relation to the quickness and slowness of the pulse. In health they correspond, and in fever as the circulation is accelerated the respiratory movements become more frequent; blood is transmitted with greater frequency to the requiratory centre, and stimulates it to discharge an increased amount of work. In double passimonia, when the blood is more vesous, the dyspaces and respiration become so increased that by this symptom alone we judge of the perilons state of the patient. When the tuberculosis is intense there is usually acceleration in breathing, and both in the morning and in the evening the respirations are above 30 in the minute. In 54 cases of the quickest pulse, the evening requiration was quicker than the morning in 25 cases; the evening requiration shower than the morning in 23 cases; the evening respiration was equal to the morning in 6 cases. In 54 cases of the slowest pulse the oreging respiration was quicker than the morning in 24 cases; the evening respiration slower than the morning in 17 cases; the evening respiration equal to the morning in 15 cases. Of the mean respiration in 46 cases the evening respiration was quicker than the morning in 20 cases; the evening respiration slower than the morning in 20 cases; the evening respiration equal to the morning in G cases.

But between the rate of the pulse and the temperature, as I have previously stated, there is no necessary relation. The temperature may be high, and the pulse slow, or not zeron. We may have a morning pulse of 140 and the temperature 57°; the evening pulse may be 180 and the temperature 95° or 96° (Wilson Fox). We must infer that the variation in temperature may be accompanied with a pulse of the same frequency; those cases which are distinguished by a rapid pulse are commonly those where the temperature is highest, and low pulses are generally met with where the temperatures are low. These conclusions of Dr. Fox accord with my experience of some other pyrexial states. Quick breathing may be associated with a slow pulse, and in exceptional cases slow breathing with a quick pulse. In one case of some tuberculosis, the quickest pulse was 136, and the respirations 28; the slowest pulse was 88, and the respirations 32. Some condition of the nervous centres due to hysteria or exhaustion may explain this.

The relation of the respiration to the pulse is more definite than it is to the temperature; the slow pulse is usually accompanied by retardation of the respiration, whether it be meeting or evening; but the pulse may be slow whilst the respiration is rapid. The pulse is more influenced by the temperature than the breathing; a slow pulse and rapid breathing may coexist with low temperatures, but a quick pulse and rapid breathing may also be associated with low temperature. When the pulse and respiration are both low the temperature is generally normal, or nearly so. Pyrexia may exist with little acceleration of either; or the temperature may be high and the pulse quick, whilst the respiration is scarcely accelerated. This applies to some other febrile states besides tulscentosis.

According to Dr. E. Smith and Dr. Fox, rapid pulses with slow breathing are not observed in the early stages of phthisis. For many of the foregoing calculations concerning the relations of the temperature, pulse, and respiration in tuberculosis I am indebted to the perusal of Dr. Fox's paper on this subject, who has collected a large number of facts from his experience and that of others.*

The two following cases are not without interest.

Case I.—Jane C.—, set. 6] years, first came under my care at the Samaritan Hospital on October 24th, 1874. She was an intelfigent child, with fair bair and gray eyes, and had grown beyond her strength. During the winter of 1873 she had had an attack of croup, and had been ailing over since. Her father and mother

^{*} Mod-Chin Trees, vol. lvi, 1971.

were healthy, but a younger brother was the subject of rickets. She was too weak to take any exertion, and in the evening was feverish and hot, with a beight circumscribed flush on the left check. It was seldom observed on the right check. The close symptoms complained of were pain in the stomach and constant sickness, so that she could retain nothing that she swallowed. She had a short, frequent, and troublesome cough, and expectorated a little thin phlogra; she complained of thirst and headache, and the tongue was covered with a thick white for; latterly, she had become irritable and folgety, and it was difficult to mame or please her. There was some obscure dulness under the left clavicle, but no harshness of breathing or moist sounds; the cardiac sounds were very distinct under both clavicles. The tenperature was 10 LN, polse 160, respiration 40. I ordered the child to be kept in the prone position until the sickness was relieved, and to be fed frequently with a tablespoonful of milk and lime-water. In the shape of medicine, citrate of potash was given in effervescence with hydrogramic acid. She was to be sponged with topid water in the evening, and if free from pain, to have a grain and a half of quinine in a powder at beltime before the panexysms were expected.

27th.—The child was better, but the flushing had continued regularly morning and evening; any fatigue or excitement brought it on. The sickness and pain in the stomach were abated, she slept quietly at night, and made no complaint of headache; the torque was cleaning at the tip and edges; pulse 96, temperature 20%. As the bowels were inclined to be costive, and the motions green, I prescribed a powder at healtime, consisting of gray powder, bicarbonate of soin, and powdered rhubarb, of each two grains.

Norember 10th.—She was much better, having had flushing of the face only twice the previous week on the same day; the sickness was completely arrested, and the bowels noted regularly every morning; the tongue was clean, and she was bright and animated; pulse 92; temperature 99.1°; respirations 24; urine clear. When the fever was off her she was to take the quinine powder three times a day. Since last visit she had taken a pint of milk daily, besides less! ten and mutton broth.

24th.—She had much improved, her checks having filled out, and her appetite amounting to hunger. The temperature was only 95°, the pulse was 140, and this probably from nervouses, as an attempt at examination was enough to cause flushing. She had flushing of the left check from overexcitement at play; it had been noticed on both checks, but generally on the left—never on the right check alone. She spat up a good deal of phlegm, and often had the feeling of wishing to clear her throat; the lowest were quite regular. Since her illness began she was generally restless in her sleep, and at these three was always flushed; the abdotom was increasing in size, and her clothes came together round the waist with difficulty. The mother noticed this swelling for the first time a week before. The region of the liver was smooth, but slightly projected below the ribs, and the belly generally was tumble and protuberant, though free from pain and tenderness. She was ordered a tenspoonful of cod-liver oil twice a day, and as much nutriment as she could digest comfortably.

On December 8th the report states that the bowels had become very loose; the motions being dark and ragged-looking; she complained of pain in her eyes, and there was hendache; since the darrhers began there had been more flushing, which kept to the left olsek; the abdomen still increased in size. There was more erugh, and some dulness below the spine of the left scapula, with nuceus thoughus. The number refused the child to be admitted as an in-patient, and I did not see her again till November 6th, 1875, when, on calling at her house, I ascertained the following facts: After her kest visit she remained ill for about a month, and then gradually regained her flesh and strength, and her body received to its normal size. The medicine was continued regularly during this time. The chest now expanded well, but the perenstion rote did not appear to be quite so clear on the left side as on the right, and there was duloses in the suprascapular space of the same side, but no moist sounds anywhere. There was no onlargement of the liver or spices, and the belly was soft and natural. Allowing for some excitement at my unexpected visit, I found the pulse did not exceed 84, respirations 24, temperature normal. The thild was in every respect healthy, and went to school regularly. see no reason to deay the possibility of a deposit of tabercia in this case, and the fall of temperature indicates its arrest, if not its Carrie

Case II.—P. E.—., set. 12, was first brought to me on the 19th of April, 1875; he was the son of healthy parents residing in an terrated district in the neighborhood of London, and had five

brothers and one sister. The eldest brother died at fourteen years of age of heart disease, apparently unconnected with rhounation. He had always experienced fair health till six weeks since, when he took cold, and had feverish symptoms at his school in Staffordshire, where the atmosphere was damp and hamid. His illness was thought to be whooping-cough, but this was doubtful, as no medical man was consulted, and after his return home his parents never heard him whoop. His second brother, who went to the same school, was lately seized with rheumatic fever, and ilkal three. He had lost much flesh, and was very thin, his clothes hanging locardy on him. He was a slander and delicate lad, with downess eyes, and a sad, wearied expression; the teins were very positiont and distended over the front part of the chest, and the spine was much curved from weakness, the lower angle of the right scapula being within an inch of the spine; the left was three inches from it. Pathicis was not hereditary, and no member of the family on either side appeared to have suffered from it. The symptoms conplained of were great languor and prestration of the strength; he had firthe inclination to enter into any amusement with his brothers. and if he did he was soon fatigued and glad to lie down. He had a short, frequent, hourse cough, and spat up a little light tenarious phlogus in the daytime, but more particularly in the morning or waking. Towards evening be got flashed, and complained of becolache and thirst; his mother noticed that he was restless in his sleep, and that the skin was hot and not sweating. On examnation of his chest the expansion was good and equal under both clavioles, though, in consequence of his having lost so much flot, the depressions above and below the clayleles were very marked, and the shoulders rounded and hent forward; the percussion-note was resonant, and the vocal vibration greater than usual; but this was explicable on the ground that the thoracic walls were very thin, and the intercostal spaces everywhere depressed.

A similar reason may explain the lond and rather harsh character of the respiration under both clavicles, but there were no moist sounds. On percussing the back the dulness was greater in the super-spinous fossa on the left side than on the right; but in the absence of submucous or senorous rhonehus, the result of this physical examination did not enable me to prenounce the patient tubercular when I was pressed for an opinion. I thought be was, and that in the course of a short time I should detect unnistakable evidence of such polmonary changes that all doubt would be set at rest. The skin was dry and barsh, the temperature 102°; the palse 136; the respiration quiet; bowels costive; urine clear and somalbuninous; the tongue presented a whitish coating, and the appetite for fixed was imperfect, which in genuine tuberculosis is sometimes craving and veracious. I ordered him a diet of beef tea, milk and eggs, and he was to have eccou instead of tea. In the shape of medicine two grains of quinine were prescribed, morning and creming, and a syrup composed of sprill, seems, and poppy, to soothe his cough and keep the bowels open. (Form, 64–74.)

May 13th.-He looked marvelloosly better, being fuller in the face and more animated; he had coughed less, and was never fished in the evening; his appetite was greatly improved, and he rested well at night; pulse 112; respirations 24; temperature 98%. For three days he had complained of pain in the right side, below the nipple, which was increased on coughing or taking a deep inentration; but as appointation revealed nothing abnormal, the pain was probably neuralgic or muscular. The chest-sounds were the same as at the last report, but there was some laryngeal irritation and hourseness. He was ordered to apply a warm poultice to the side at night, and to use a sponge-lath with Tidman's sea salt. every meening. A mixture containing hypophosphite of lime, quinine, strychnia, and tincture of perchloride of iron was substituted for the simple quinine mixture." This is an excellent evenlimition in cases of aniemia and nervous exhaustion, and the slow blood-change which occurs in the diatheses of strums, syphilis, and talsurole,t

June 9th.—The larguageal irritation had not lessened, and the cough was backing and troublesome in the morning, but anattended with expectoration; there was no sweating, and he slept well. Nearly three months later (at the end of August), after

gaining flesh and going on remarkably well, he became faint and languid and lest his appetite from indiscretion in diet. He was irritable and fretful, and nothing went right with him, which was attributable in a great measure to over fatigue and excitement in the hot weather. His veice was now clear, and he did not suffer from cough or laryngeal irritation. The chest-sounds were normal. He derived the greatest benefit from the hypophosphites, and a

mouth later went to Brighton apparently well,

I might relate other cases of a mixed and puzzling character, allied to genuine tuberculosis in many of the local and rital symptoms. If the lungs and other organs appear to be free from the deposit of tubercle at the time a patient comes under observation we may pronounce the illness as simple and uncomplicated, and give a favorable opinion, because recovery, so far as I have been able to trace the progress of the disorder, has semetimes followed the continuance of a class of symptoms which have been the closest connection with what appeared to be at one time as irremediably hopeless condition.

We will consider the treatment in the next chapter.

CHAPTER X L.

PHYSISS PULMONALIS OR PULMONARY CONSUSPTION.

Definition of the term. Nature of the discuss. Analysis of the Mond in philitis. Ir may be well now to consider the disease called phthisis from a special or clinical point of view. Already I have referred to it with regard to its relation to tuberculosis. Now there are forms of phthisis not clearly tubercular, but as tubercle bears so close a relation to this subject, I must again repeat much of what I have said in the chapter on tuberculosis, just as in that chapter I was obliged to anticipate much that will be said on phthisis here.

The usual acceptation of the term pulmonary phthis means waiting away. It is a constitutional rather than a local affection, associated with malautrition and a depraved state of the blood, leading to destructive disease of the lung. In England it is both common and fatal, on account of the variable temperature of this cauntry. It sparse mother sex nor age; but the poung are its special victims." As we have said before, when speaking of taberculosis, phthisis, which in its commonest types is allied to that disease, is often associated with a certain delicate physical beauty, and with high mental qualities. The gradual sinking and death of a typically phthisical subject has a painful, yet pictures one aspect, which has not escaped the notice of artists, poess, and writers of works of fiction. Those who are fair and beautiful, reduced and accomplished, successibly or gradually to its rayages.

The leading constitutional symptoms which denote its presence are a gradual decline in the general health, and a persistent and harassing cough, with little or no expectoration at first, acceltrated breathing and pulse, febrile purexysms, nightsweats, disturbed sleep, emaciation, diarrhou, and occasionally sudden death. The physical signs are those of pulmonary congestion, followed by consolidation, and eventually by the breaking down of the lung itself.

The peculiarities which distinguish the deposition of tubercle in early life cannot be too strongly insisted on and understood, for they are strikingly different to what we observe in later years. In

^{*} Of 544 cases noted by Dr. Austin Flint, only one come accurred under ten, and cunball'the cases occurred between tenanty and therety. Dr. Dobell's Reports on Discusses of the Chest, eq.(u., 1876, p. 19.)

children there is a tendency to the diffusion of tubercle in the chief internal organs-as the brain, the langs, liver, spleen, kidneys, broughful and mesenteric glands, whereas in adults the pulmonary organs are remarkably prone to suffer. The disease may confinue in one lung for years, and ultimately cause death without spreading to the other. Cavities are not common in the lungs of children. though I suspect that in catarrhal phthisis they are of more frequent occurrence than is generally supposed. Certainly the carities are smaller, and they are sometimes numerous. This general diffusion of tubercle in children lends considerable support to Dr. Wilson Fox's view, that pulmonary tuberele is a primary growth, and the changes that subsequently snow are owing to inflammation." This of course involves the question of hereditary liability, and a state of the blood and tissues favorable to the tubercular dyscrasia. Dr. Ambrow Clark notes a different view, as the following extract shows:

"The generic term (phthisis) comprehends all progressive consolidations and circumscribed supportative disintegrations of the lungs; the specific term should indicate by a distinct adjunct the different states consurring to this end. For surely if the progressive consolidation and supportative destruction of lung constituting phthisis be determined in one instance by tubercles, in another by promonic exudations, in a third by scrofulous growths, and in a fourth by fibrons instances, and if these things be in any sense different from one another, common souse demands that their differences should be permanently resorded by distinctive designation. Hence it is both convenient and correct to speak of tabercular, scrofulous, pneumonic, fibrons, and bronchial phthisis."

We have now to inquire in what the disease consists, how it

originates, and what is its true pathology?

These are questions to be answered before we can preced to discuss its cames and its treatment. In ascribing it to a defect or disturbance in the functions of any particular organ or tissue, we have still to inquire in what the meebid action consists. Is it not due to some primary blood change, which alters the nutrition of the body, and deranges the circulation, thus leading to explation of materials of a low standard, incapable of absorption and irritating to the organs in which they are deposited, and thus by causing

^{*} Truss, Path. Soc., 1871.

[†] Clic Trans., Case of Fibraid Pichine, by Andrew Chek, M.D., 1804, p. 185.

the production in them of fresh growths, involves them in destruction and decay. This seems a reasonable hypothesis, if, as I have pointed out in the previous chapter, the subcutaneous injection of inflammatory products, or tubercle itself, can originate the disorder in some of the lower animals."

There is cell growth of imperfect formation with a great tendency to die, the more rapidly the cells are formed the less vitality they have. Healthy blood determines a healthy performance of all the organic functions, digestion, nutrition, circulation, scretion, and excretion; but when it is diseased or altered from that of bealth, then indisposition in some shape or form arises. Some function departs from its normal condition; and where the tubereniar habit is present a morbid change ensures, which lends to the formation of tuberele, just as some other habit of body may develop another organic disease.

We can no more conjecture what determines this particular change than why children of the same family differ in physical form and mental capacity. It is an inscrutable law beyond the

limits of our understanding.

drive Philipia (neute tuberculosis). I have briefly alluded to this in the last chapter, and quoted a case by Dr. James Russell, of Birmingham, in which the lungs were studded with tubercles, and yet the patient had no physical symptoms before death beyond mpol breathing. It was evidently a case of acute phthisis, such as we sometimes see in young subjects following cold, and in whom there is a constitutional liability to the disease. The disease is so rapid and violent in its character, that there is no time for the action of remedies, and it runs its fatal course in a few weeks. The absence of physical eigns when a few tubercles are deposited through the lungs is common enough, and we often see this verified in the post-mortem room. In such cases, there is frequently no daleses on percussion, and no alteration in the breath-sounds. When millinry taboreles are thickly deposited through the lungs, there will be found general bronchitis, announced by thouchus and shilms, the chest may or may not be dull in places, and the pulse and respirations are accelerated. The weakness is very great, and the wasting of fesh general. In the autumn of 1879, I was requested by a neighboring practitioner to see with him a log ten years of age, who was dving from pulmonary disease. Several

⁸ See Chop. XXXIX, On Tutoculosis.

members of the family had died of consumption. He had been only ailing a mouth with rheumatic pains in his joints, and had had no cough till within a few slays of my visit. We found him sitting up in bed perfectly collected and intelligent, but terathing rapidly; the livid lips, the pullid face, the coldness of the hards, and the failing pulse, told of his approaching dissolution. The chest was resonant on percussion both in front and behird, but universal rales were heard throughout all diameters of the broschial tules, which were enormously loaded with success. Below the spine of the left scapmia, the lung was evidently breaking down, judging from the cracked pot sound on percussion, and the brouchial breathing. I suspect that the other portions of the lungs were filled with gray granulations, and some of them were passing into cassous change. The patient gradually became worse, and died in about thirty-six hours after my visit. No post-norten examination was permitted. "They (gray granulations) break ant simultaneously, like the eruption of an examthem, and by their numbers and bulk induce such an amount of obstruction and congestion of the lungs, as to destroy life before there is time for any considerable degeneration or softening to take place. This worst independents in the worst and most surely fatal form of couenmpdion."

Another form of sexte phthinis is that which commences with inflammation in one or both lungs, loss of appetite, dry lips, red tongue, thirst, cough, and expectoration. There may be hamaptysis. There is usually high fover, the temperature reaching 100° in some cases in the evening, quick pulse and accelerated respiration, followed by chilliness, and sweats at night. The physical signs, if limited to one lung, indicate the singe at which the discuss has arrived, from dulness on percussion arising from consolidation to the cracked-pot sound, and tubular or bronchial breathing with coarse crepitation. Death may take place in a few weeks. After death the lungs are found consolidated and hepatized from inflammatery disposit, and in places the yellow matter is breaking down into cavities. It is this form of discuse which has received the name of golfsplay convenueton. "To my mind, what some certain in this form is that aregistus imflammation, scattered

^{*} Pulseware Communication, by Dec. C. J. R. Williams and C. Throdore Williams, 1874, p. 2.

broadly through the pulmonary substance, causes its rapid and extensive disorganization."

In treating of the pathology of broncisopasumonia, I mentioned that it sometimes ended in tuberculosis and caseous change. This is really one of the forms of phthisis called "Catarrhal Phthisis," the result of inflammation. It is therefore implied that phthisis is sometimes due to inflammation which has clogged up the nirvesicles, and at others to degenerative changes, to adenoid or lymphatic, throughout the pulmonary tissue, in which the bronchi have no share in the morbid process. That form of consumption in which miliary tubercle is scattered through the long without breaking down of its tissue into destruction and cavities, I have spoken of in the last chapter.

Commission is a form of phthisis prope to follow the brouchopnoumonia of an exanthematous affection, especially measier. It is essentially a pneumonic disease, and does not one its origin to tuberele. Extensive easeons changes may take place in the consolidation resulting from bronchopneumonia, and the child may be in fair health, till an acute febrile disorder reases the exudation into activity, fresh centres appear, and the long softens and breaks down into cavities. Where carrities exist after death, fibrous tissue sometimes circumscribes them, and binds the long to the chest-wall. I have known one lung perfectly solid from caseous consolidation in a chibl five years of age, who had scarcely any cough, and no febrile disturbance till measles supervered, and then the lurking mischief was at once excited, and death took place a few days after the disappearance of the rash. After death there were two excities in the left lung which showed recent formation. There was no healthy lang-tissue. The right long presented no trace of disease, but tuluroles were found in the liter and spleen, and there were also enlarged bronchial and mesenteric glands. "This condition is the yellow tubercular infiltration of Lacance, the scrofulous pneumonia, caseous pneumonia, or tulerentar puentoonia of different modern writers."

When phthis is chronic, and is seen in connection with tuberele and with fibroid those, it is termed "mixed phthis "! The presence of tubercle in the affected lung cannot always be discovered; the disease is sometimes acute, and involves the whole

^{\$ 15}th, p. 564.

of a long, while in another it is more partial and chronic. It is difficult, if not impossible, to frame definitions which shall include all these varieties. After all, they are merely different stages of the same morbid process varying in extent and degree

The following is an interesting case of eatherful phthicle traceable to inflammation, and in which, as I have just stated, the tubercular condition was followed by marities in both lungs.

M. C, set, 4), was admitted into the Samaritan Hospital, under Dr. Wynn Williams, November 4th, 1878, with a temperature of 101.8°; pulse 140; respiration 69. A year previously she had had whooping-cough and broughitis, followed by diagrhou, and subsequently failing health. There was a history of half starration, and the child was meany and exhausted. An examination of the clust rerealed dulness over the right sternam, loud tobular breathing mixed with coarse crepitation, and the voice was brouchophomic. The right long was resonant before and belind, and the respiration was exaggerated. On the 16th the morning temperature was 99°, and the evening 104°; the pulse and requiration were the same as on admission; the cough was loose, the lips were ducky, and riles were heard throughout both lungs. On the 22d the morning temperature was 20°, the evening 1024°, pulse 156, respiration 44, abdominal; the eyes were dull, and the lips dark and dryish. There had been slight wandering at right since admission. There was an enormous accumulation of phleguin the air-passages, and tiles were distinctly audible throughout the front and back of the classt. The carotid arteries heat actively. and the external jugular voins were distended from defective action of the right heart; pupils turned up under both eyalds; belly flat; urine high-colored, but monalbuminous; copious discharge from both ears. On the 27th there was load premueofe erepitation in the lower half of the left long, which was dull on percussion; above, tubular breathing. There was subcrepitant rhosebus in the lower half of the left lung, and slight dulues. There was a slough behind the left ear, over the mastoid process, just as is scenedimes seen over the sacrum in fever. From this time forward to her death (December 2d) the temperature did not exceed 100°, but the pulse and respiration were unchanged.

Postmerten Econometics, torsely hours after Doubl, by Mr. Allen Doren.—Body much cancisted, and large slough around the pinne of both cars. Lungs studded with caseous tuberds. Nocrosis of squamous and petrons parts of laft temporal bone. The right imag was pale and emphysematous. There was a steader old pleural adhesion near the apex, a small cavity near the apex, and a calcified tubercular deposit in the middle lobe, and pacumonia at the base. The left lung was almost universally atherent to the thoracic walls, and infiltrated throughout with tubercular caseous deposit. There was a cavity large enough to bold a walant near the apex, and much pacumosic change at lose, with easeous tubercle. There were about two ounces of turbid serum in the pericardium. A broken-down lymphatic gland filled with pseudo-pus lay close in frent of the nortic arch. The heart and brain were normal. The lives was large and studded with tubercle. The splean contained a few caseous tubercles.

Obronic phthinis (tubercular phthinis-chronic telerrolosis) is the most common variety of consumption that we meet with. It seems in the form of miliary tuberds, which usually selects the apex of a lung, instead of being thickly disseminated through both lungs, as in neute tubercubuls; bence the complaint is not so rapid in its progress, and there is a better chance of the disease being arrested, or followed by complete recovery. Following these granulations there is cascation, which causes consolidation of the apex, and ultimately softening and degeneration. The centre of the mass softens and breaks down into a cavity, whilst the cirrunference becomes harder and fibroid in its structure. It is supposed by some authorities that all the changes can occur without the presence of tubercle, as it was once thought that all the morbid changes were primarily due to tubercular deposit. It is in such cases as these that we hear of the complaint being arrested in its first, second, or third stage, and cavities remaining quiescent for many years. There may be a difference in the changes which take place in chronic cases, because, whether tubercles form early or late, they are always complicated with inflammation; the discan may begin with inflammation, and as it advances become tulercular-tubercies added to pre-existing inflammation

The destructive process having begun in the agex of the lung gradually proceeds downwards, and the cavity, when of any considerable duration, presents a different appearance to those cavities which subsequently form in the centre or lower parts of the lung. The walls of the cavity in chronic cases of pulmonary discuss are dense, tough, and hard; they are lined by a membrane which is more or less vascular, and pours out a free secretion. "Cavities thus fined may continue to yield for some time a purulent scretion, which gradually lessens in quantity, and all active signs of disease elsewhere having abated the case becomes one of 'quicavat sority," The process of destruction having been arrested, the dense cartilaginous tissue surrounding the cavity undergoes contraction, and so in time diminishes its area. Those cavities which are recent have no defined outline; their walls are ragged, soft, and irregular, and may contain pus or broken down lung-tissue. I have recorded such a case in a boy, where the cavities were very recent, although the lung disease was of considerable standing. "Thore has been no indunation of any part by the development of connective thoug, but the whole lung is crowded by soft, relier, albuminous, or scrofulous matter, which has undergoue so rapid a softening that the whole lung resembles a sponge sorked in puralent matter." In the case to which I have alluded the whole long, except where the two cavities existed, had the appearance of a Stilton chose, where the white and sage looking green parts are almost equal. It is a scrofulous material which tends rapelly to execution and decay. There is no repair, or the possibility of it, in any lung so extensively infiltrated with this deposit.

When these changes are taking place in a chronic earlty of some standing, the bloodyessels become impervious, and thickened by hard lymph, hence hemorrhage does not occur when voniting or severe coughing ensues. The bronchial tubes do not, formsnately, share the same fate; their destruction proceeds with that of the polmonary tissue, and hence they remain pervious. It is through them that the products of alceration and suppurstin

make their way out of the system.

Privoid phthicis (circlosis of the lung-Corrigon) is that variety in which the consolidation of the long has undergone a fibrous induration; it is tough, and becomes contracted when the pulmorary tissue is compressed from plearogneumonia, so that no exudation is thrown out into the air-cells, and the plastic natter is confined to the intersticial texture; if not reabsorbed it leads to contrac-

² Pulsebasical Austrony, by Wills and Moges, 1875, p. 344.

tion and consolidation." In this disease the brouchi are dilated, because as the air enters the chest it cannot obtain admission into the air-cells.) Hughes Bennett, Addison, Wilson Fox, Bartels, and other authorities, have shown that dilutation of the brouchs is a common consequence of bronchopneumonia in children, and that this dilatation disposes to thickening around the broughi, and to induration of the pulmonary tissue. The parts surrounding eavities are often dense and firm, " and the process of cicalrization of such cavities is almost always affected by the production and contraction of a filtrous tissue of a similar character." The disese may arise from poenmonia, or from pleuropnemionia, when the effusion thrown out into the interstitial texture of the lung becomes transformed into a tough fibrous-like tissue, "Fibroid twices may arise from interlobular inflammations, from long-conthroad chronic broughttis, from the extension of dry pleurisies into the long, and from the transformation of pneumonic exudations. They produce contraction and induration of the lung, and occadonally dilatation of the pulmonary tissue of the bronchial tubes. Sometimes fibroid lesions load to ruseons pneumonia and to "tuberules;" more frequently they occur alone. Their elinical history is characteristic; it is slow in its progress, apyretic in character, and somer or later produces albuminaria and dropsy."5

Dr. Pollock states that "Breachito is a less common origin of fibroid changes, but it is observed in children and others; in the farmer after pertussis or rubcoln, when collapse of a portion of lung is upt to occur, followed by contractile fibroid proliferation."] Dr. Wilson Fox also writes: "If we consider the course of neute broughitis in children, and recollect how constantly dilatation of the brough occurs in this condition, both in the idiopathic form of the disease, and also in the course of measles and whoopingcough, it can only be a subject of susprise that permanent belows of this nature are not more commonly met with as the results of these diseases."

This sequence of events looks very much like the blood having also undergone some important changes. "But there is also, prob-

Erynolde's System of Medicine, asticle Chronic Processonia, vol. 88, p. 756.

aldy, a peculiar fibrinous state of the blood, which Rokitansky calls a Orizons events, in certain cases, rendering the predicts of inflammation more fibrinous than usual, and with smaller propertion of the corposcular element; and tending, therefore, to produce more fibroid so contractile tissues, and less of the puralent and opaque carrly deposits which originate in the corposeles or surrophytes." There may be differences of opinion as to the manner in which the disease originates, but the tendency is to come contraction and induration of the texture in which the meetid matter is deposited, and sometimes to In followed by essention and envities in the lungs. The bronchial tubes also become dilated or contracted according to the part of the lung which is chiefly affected. When the lower part is invaded the air cannot get be youl the larger tubes, and so the pressure of the inspired air dilates thun; while, at the upper part, the tubes are contracted from the shrinking of the lung towards the spinal column, the collapsed state of the chest-wall, and the displacement of the heart upounds.

"In characteristic cases of this nature, the cut surface of the lung is smooth and glistening; it is hard, and creaks like cartilage, or resembles the tissue of the aterns. It tears with the greatest difficulty, and no longer presents the granular appearance of ordinary pneumonia. No fluid can usually be expressed from this tissue."

The constitutional symptoms of phthisis in some cases are slow and insidious; they are frequently overlooked till attention is invited to the class, and then the presence of physical signs is too often conclusive. Illness has begun with slight catarrh, broachitis or pleurisy, or presuments, and the child has not been redafter it. It gets a severe sold, followed by pain in the chest, cough, and quick brenthing; it improves for a time, and then gues another cold, which is more obstituate, and if any expertoration is seen it is equippe, and perhaps streaked with blood. As the case goes on, the temperature rises towards evening, sleep is disturbed at night, and the pulse and respiration are habitrally quick. If the child losse appetite it wastes rapidly, there is thirst, it is fretfal and invitable; the bounds are irregular, constipation is often present at an early stage, and diarrhora later on. The

^{*} Pointerry Convergeon, by Do. C. J. E. and C. Theodare Williams, 1871, p. 63.
1 Wilson Fox, ep. ch., p. 267.

motions are greenish and loose, or clayer and offensive, and the abstemen is often large. In a case of chronic tuberculosis in a child 63 years, who came under my care in 1875, the illness had only become observable to her friends a fortnight before I saw her; but the child was strumous and delicate-looking, and had been kept hard at her lessons till she broke down. She was fast being flosh, and was harnt up with forer at night, yet there were no chest symptoms, and no cough or expectoration; the pulse averaged 120, morning temperature 19°, creating 101°. She persimed under treatment for six months, and when I saw her then she had not improved; there was a little cough, a pulse habitualty quick, and a temperature always above normal in the evening.

Hemograpis is another important symptom, but it is not frequent among children as a symptom of phthisis. Still it does occur now and then, especially where tubercular or pneumonic sonsolidation is breaking down. In an early stage it is due to active hypersenia, to an unfine determination of blood to the congested mucous membeane, and not to venous obstruction. In advance phthisis it arises from aneprismal dilutation of branches of the pulmonary artery being ruptured, and is rarely bronchial, whereas, in early phthicis, it is generally bronchial.* In bronchopseumonia and whooping cough a little blood is frequently coughed up from prerdistension or fragility of the capillaries, and the patient is ness the worse for it. I have known a child, 3) years of age, burn of consumptive parents, and suffering from tuberculosis, bring up at one time a tablespoonful of blood, a year before any other chest symptoms were noticed. This kemorrhage was then followed by less of flesh, intense thirst, and febrile exacerbations towards evening. Small mucous rides were detected over the frost of the chest and below the spine of the right scapula, which area was also dull on percussion. There was harassing cough, and thick sputa were coughed up, occasionally tinged with blood. Hamorrhage from the long would seem to have been the startings point in this case-the real cause of the lung destruction. "Our experience of many thousand cases has led us to conclude that hemorevels to the extent of more than a draches in a person free from the hemorrhagic diathesis, from cancerous disease of the long, injury to the chest, disease of the heart, and from disor-

Dobeil, ep. en., μ, 20.

der of the uterus—is indicative of a fragile state of the vessels of the lungs, closely connected with, and generally arising out of consumptive disease of those organs."

Homophysia is less copions in the first than in the third stage of the disease. Dr. Douglas Powell has recorded a fatal case of homoptysis in an infant seven months old. Five other children of the same family had all died consumptive; the father had thest disease, and the grandfather died of phthisis at thirty three, "Without having had any previous attack of homoptysis, the infant suddenly expectorated more than half a pint of dark ciented blood, and died almost immediately. On a post-mortem examination the surfaces of both lungs were studded with solpleural gray military granulations of tuberele, and the lungs, on section were also found to be disseminated with gray granulations."+ It has also been stated, in corroboration of Niemeyer's view, that in cases of severe homoptysis portions of blood are drawn into the alveoli, which they occupy as fibrinous nedules, and that these may set up irritation, produce a calcurcous mass, or even cause laceration of the pulmonary tissue and cavities.]

The physical signs of phthisis ought to be carefully studied, because they throw light upon the general symptoms of the discuss, and strengthen our diagnosis, when the indications affected by either alone might leave us uncertain. Phthisis is both a constitutional and a local malady—constitutional in the sense that it has a preliminary stage, if I may so term it, and the patient may be communitive without my tubercie in the lung. The local change, when it does ensue, is the effect of the constitutional taint. Many children present all the general characteristics of pulmonary consumption—wasting of flesh, quick pulse, and harming cough, and yet the chest affords no evidence of disease; the resonance is not impaired; the breathing is clear.

I have before said that tuberele tends to diffusion in young subjects rather than to concentrate itself on the spices of the lungs, as it does in adults. Still we occasionally encounter was in young subjects where the morbid changes do not extend to the base of

⁸ Palanaury (convergeion by Drv. J. C. H. and C. Threshaw Williams, 1974) p. 145.

^{*} Path. Town, 1974, p. 48.

the lungs, or if tubercle is scattered extensively through them, it mainly involves the upper lobes, and softening takes place before the patient has lived long enough for the like destruction to cusus in the lower lobes.

We shall speak of three stages of the disease:

- 1. That of deposit.
- 2. That of consolidation and softening.
- 3. That of suppuration, when cavities form.

Space will not admit of fully considering all the signs which various authorities have from time to time held to indicate consumption. I am bound to admit that my own experience concurs with those who are unable to declars whather more feebleness or harshness of breathing, imperfect expansion of the chest, londness of the heart's sounds, or brouchophony, are, any one of them, taken singly, reliable indications of tubercular disease. I think not

Although it is important to examine the chest carefully throughout both in front and behind, the upper portions of the lung above and below the clavicles, and the suprascapular spaces, should never be overlooked. The interecapular region too often affords evidence of enlarged brouchial glands, which may serve to clear up any death.

First Stage.—Looking at ordinary cases as we meet with them in practice, the earliest indications of a deposit of tubercle in the pulmonary tissue are an alteration in the breath-sounds; the inspiratory nursuar is weak, harsh, jerking, or brouchial, and the expiration (which is far more significant) is load and unduly prolonged. Mere weakness of breathing does not go far as a diagnostic sign, as it occurs in many cases of general debility, and disappears with improved health. It may arise in consequence of a narrowing or obstruction of the bronchioles, plauritic effusion, thickening of the plaura, and emphysema, which impair the clusticity of the lungs.*

A comparison of the two sides of the chest is the only test of its quality, since it is very rare to find both lungs similarly involved.

Hirsdores of breathing is another sound at variance with the softness of health, and when also rough or blowing it passes into breathing with moist sounds. It arises from thickening and less of clasticity in the air-cells, and also from a dry condition of the broughful membrane.

^{*} Clinical Demonstrations of Philipine, by J. D. Pollock, M.D., the Lauces, vol. ii, 1976, p. 179.

When there is a change in the quality of the breathing, and the expiration is prolonged, it may be considered to indicate communing mischief. In some states of delility among children, and in bronchitis and emphysema, audibility and lengthening of the expiratory murmur are not uncommon. This is very apparent in thin exhausted subjects when they allow the air to escape from the lung by a sudden or spasmodic effort, as they often will do when the chest is being examined. We have all observed in practice how short the inspiration is, compared to expiration in far and fooble subjects, when the heart is weak and the patients are breathless from flatulance or exertion.

Jerking, song, or interrupted respiration is only valuable as a means of diagnosis when taken in connection with other signs. Alone it is unimportant.

Changes in the form and movements of the thoracic malls are worthy of careful observation, as throwing much light on the condition of the lung. When the patient is placed in a suitable position, and the hand is laid over the sternum during inspiration, a comparison of the two sides can easily be made, and any inequality of expansion is detected through the amount of tubercular deposit. The other retrogressive changes are the sinking-in of the thoracie walls, the emp-shaped depression below the clavicle, the remided shoulders, the bent form, the contracted chest, and the distorted spine.

Deleces on percession is another diagnostic sign on which goal reliance has been placed, and it sometimes comes to our ald; but it is not always present, as I have pointed out in enumerating the physical signs of tuberculosis. There may be considerable intercular deposit scattered through the pulmonary tissue without enusing any dulness whatever. Still in that variety of phthisis in which there is a localized deposit of tubercle in the apex of a larg, there is diminished resonance or heightened pitch.

Vocal fressitus is another physical sign to be restembered. It is dependent on the extent of pulmonary condensation beneath the thoracic walls, but it is not always present, and there are usually other signs of more significant import. Children's chest-walls are thin, and the normal vibrations are readily conveyed through them; fremitus, therefore, is often present when there is no disease. "We may, I think, conclude that whenever there is an equal amount of vocal fremitus in both infractavioular regions the left con the left than the opposite side it is almost certainly so." Regarding bronchophony, another valuable sign, the same writer remarks: "If there be an equal amount of bronchophony in both infractivitation regions, the left is probably morbid; and if there be a positive excess on the left side, it is almost certainly so; a greater development of vocal resonance, however, on the right side, is no indication of tubercular deposit, although it may be backed upon suspiciously should the excess be very highly marked." Undue propagation of the heart's sounds, subclavian or pulmonary marmours, are all signs of some assistance in suspected tubercular consolidation.

Meist sounds heard at the spex of a lung at the seat of tubercular deposit are very significant. There is a sound called dry medfing rhoushus, which is regarded as conclusive evidence of taberele. It is a dry and crackling sound, generally heard during inspiration, and indicates an advanced condition of the first stage. Those crackles are at most three or four in number, and are prodoesd external to the air-cells; they are not always heard, and they are succeeded by a moist kind of crackling. The sound is and unlike suberspitant rhonolous, which is, however, moist and bubbling, and can scarcely be mistaken for it. Subcrepitant rhonthus, however, succeeds it, and if heard at the apex is very sigsifcant, although if broachitis be present it may be heard at the hase also. This sound passes into humid grackling. If there is dry cough, a little florculent expectoration, with febrile symptoms and any loss of flesh, the early stage of phthisis is confirmed. Dr. Pollock has known the stage of deposit to remain quiescent over and over again for fifteen or twenty years.;

If phthisis is the consequence of bronchitis, the signs of the latter disease are increased, rhonehus of a sourceus or sibilant character is heard below the clavicles and over the greater part of the sternum, as well as between the scapelie. If these sounds are persistent, and are more heard at the upper portions of the lungs than at the lower, they are suspicious of early phthisis, especially if the resonance on percussion is impaired in places. If also subcrepitant rhouchus accompanies the expiratory as well as the in-

1 Op. oit, p. 179.

+ 11-d.

^{*} Phthisis and the Stethoscope, by B. Payne Conto, M.D., 1804, p. 25

spiratory murmur (which, according to Dr. Williams, the cropitation of pneumonia never does), then this view is the more suspicious.*

Cregitation is a sign of obstruction to the entrance of alr into the pulmonary tissue in consequence of swelling, or the presence of secretion in the aircells. When phthis is the result of acms pneumonia, the dulmess on percussion continues, and there are bronchophony and tubular breath-sounds. After a time this chronic consolidation undergoes change into fibroid or enseem matter, in the one case contracting, and in the other breaking down into one large cavity, or several small cavities.

Scored Singe.—The physical signs announcing the commencement of the second stage, or that of softened tuberole, are much the same as those already described. Seeing that the first stage may continue for an indefinite time, it is difficult to draw the exact line of domarcation between them. A tubercular mass may reach a considerable size is one case and produce extensive disease of the lung and pleura before it begins to soften, whilst in another exact degeneration takes place in the mass at an early period. A very important sign of this stage, particularly if it is at all advanced, is increased dulness on percussion of the affected side, and the note has sometimes that particular jarring, hard, dull sound which is termed "scooles," It is not a frequent sound. It seems to be produced only when consolidated lung is bound to the shoracle wall by thickened pleura (Cotton)

There is another sound, called hunsid conciling risonehus, which may or may not be preceded by dry enachling. It consists of a few moist, large, clear, abrupt, clicking sounds, of varying intensity, generally during inspiration, but they may be heard during expiration also, masking both acts; this clicking is also due to softened tubercle—to destruction of lung tissue, and when once heard cannot well be confounded with subcrepitant chouckes, which is of a bubbling character; and if the two sounds are present at the same time, which is possible if there is congestion or inflammation around the softened lung, the distinction between them is all the casier. This click in the course of time becomes louder, moister, and more or less matellie, subsequently passing into the third stage, or that of gurging rhenchus. When the clicks are slow and few, and occur at intervals, the mischief in the

^{*} Polisconery Consumption, 1875, p. 168.

long proceeds much slower than when they are large, metallic, museus, and loose.

In this stage there is often wasting and loss of flesh.

As we have seen, there is a difficulty in separating the first from the second stage of phthisis, so there is an equal difficulty in defuing the termination of the second stage and the commencement of the third.

Third Steps.—This is reached when a vomica, however small, is present. Now, the clavicle on the affected side is more promisent, and the hollow beneath it is deeper and more cup-shaped towards its acromial end. On deep inspiration the lower part of the elect-wall is elevated, suddenly raised, as it were, by the contraction of the diaphragm; the forced muscles of inspiration cone into play, whilst the upper part of the sternum is larely expanded at all, and the hand may not be elevated on the deepest inspiration.

Gargling rhandur is a moist, large, bubbling, metallic sound, beard during the act of inspiration and expiration when the cavity is small. It is the final stage of the humid crackling and large subcrepitant rhondous which have been already explained. The percunion-sound is necessarily subject to great variation, according to the state of the bing, the adhesions that have been formed, the force employed in striking the thoracic wall, and the size of the cavity. The note, from bring absolutely dull or "scoolen," is sometimes scarcely altered from that of health. I have known the infractarionlar region of a child approach healthy resonance, when the sounds elicited by anscultation and the depressed and innefire state of the chest-wall have confirmed the last stage of phthisis. When I relied mainly on percussion as a means of diagnosis, I was often in doubt as to the state of the lung. When the comica is large, and situated near the chest-wall, or only separated from It by thickened pleurs or long, the percussion-note has a peculiar hellow-like resonance, which has acquired the expressive term suplaric. When this sound is present, a modification of it, called the weeked put sound (breit do put fill), first described by Laconer, may sometimes be heard, if the chest over a cavity is struck andsenly, rather foreibly and abruptly, whilst the patient's mouth is kept open. This peculiar sound can only be produced when the ratity is large, and freely communicates with the bronchial tubes. "In children, however-the subjects of bronchitis or emphysema, and even sometimes when in perfect health—the natural percussion now and then bears a very close, or even a complete, resemblance to the cracked-pot sound; so that in patients who are young —say under ten, or at most swelve, years of age—this sign is of no value in diagnosis, unless accompanied by other evidence of the presence of a vomica,"* and unless it contrasts strongly with the other side of the chest.

A cavity may form so gradually in the lung, and the process of disintegration may be so slow as to escape notice, till the character of the breathing decides the doubtful point.

When there is a cavity in the lung, the expiration may assume a hollow, blowing, metallic quality, termed orrerous; and if the eavity is large it may possess an amphoric quality, a sound which resembles blowing into an empty bottle. Cavernous respiration is not unlike broughful respiration, but the latter is beard over a greater extent of lung, it is rougher in quality, and is unuting in the metallic type so characteristic of the former. If a cavity contains much purulent matter, or the broachial tubes opening into it are clogged up, and the patient is very feeble, it may exape notice altogether. The gurging rhoushus, too, when it is large or bubbling, according to the amount of secretion, may also obliterate the cavernous character of the breathing. Coughing will often throw much light upon obscure symptoms. " It is oftentimes by no means easy to detect the vonion of very young children. In such little patients the natural respiration over the entire chest is negally so blowing, that it is apt completely to mark the cavernous character of any particular spot. All the physical signs, indeed, but especially those derived from percussion, and the ausenbation of the breathing, are, in young shildren, at their minimum. Cavernous rhoughus, when it exists in these cases, is, parliaps, the best help to diagnosis, being less likely than any other sign to be either obscured or overlooked."4

Metallic sintling is sometimes heard when the vession is very large and contains fluid; but I never remember to have seen an instance in a child, owing perhaps to the sarity in them of tabercular encavation. Poctoriloquy, for the like reason, is not a frequent sign.

Elastic tissue is sometimes detected in the experioration of

^{*} Phillips and the Southerneys, by R. Physic Cotton, M.D., 1866 p. 72.

Phthirls and the Stethorope, 1864, p. 54.

phthisical persons who have cavities in their lungs, but it is not always found. The best method of proceeding is to beil the sputa with a solution of caustle sods, and then to examine the deposit under the microscope, "Bronchial tubes may be recognized by their branching form, and are sometimes accompanied by fragments of bloodvessels. When only small crepitations can be locard in the lungs, the greater part of the deposit will be found to consist of air-colls; where the signs of a cavity are present you will meet with portions of the bronchial tubes in the sputa; fragments of the bloodvessels can be rarely detected excepting just before or during an attack of hemoptysis."

The physical signs of the tubercular form of scute philips have been considered when treating of this affection under the latter

bearling.

Philiscol Largogitis.—When the larguageal muccus membrane is alcerated, the respiration over the trackes is harsh and load, and the voice is changed to a whisper in some cases. With these appropriate those of ordinary phthis is are generally present.

Casua.-These are predimoning and exciting. Among the fornor the tubercular or phthisical diathesis is to be noticed, with its light hair and eyes, fair skin, long eveloshes, and thin lips; so that, looking at the matter from a hereditary point of view, we know when a child has inherited a scrofulous constitution or has come of tuberenlous parents; the disease under these circumstances is readily lighted up on alight provocation. Residence on a wet soil or in badly-ventilated homes may indure it. It is a remarkable circumstance that phthisis is red found in certain countries and localities. Dr. Leared says: " In Icoland no phthisis exists; the atmosphere is cold and clear, and the inhabited parts are not much above the level of the sea. In Morocco, where there is also no phthisis, the atmosphere is the reverse of Iceland, and the soil is sandy ; there is also no phthisis in the valley of the Jordan, which is eighty to ninety feet below the level of the Mediterraneau, and the atmosphere of these three places is totally different from that of Davos," Dr. J. H. Bennett also writes: " It is worthy of remark that the inhabitants of Iceland, living in a most unlargionic state, filthy in person and habits, and cooped up in hally-ventilated Difs, are said to be all free from consumption, and from other forms

^{*} Mollical Diagnosis, by Dr. Penwick, 1876, p. 83.

⁺ Med. Soc. Proc., vol. iv, p. 259.

of tubercular disease. This fact is not improbably connected with their great consumption of oil as an article of diet."*

Among the exciting causes, we must consider the effect of previous inflammation of the longs, frequent catarrh, hereditary syphilis, prolonged amends, and exhausting illness following the oraptive fevers.

Diagnosis from Typhoid Ferer.—Acute phthisis is attended with such high fever that at an early period of the illness it may be mistaken for typhoid. The chief diagnostic differences are the natural form of the abdomen, the absence of the rese spots, gurgling in the right illuc fossa, and constipation rather than diagrams. Then, too, the cough, livid countenance, and dyspaces, point to the chest as the primary source of mischief.

Treatment,—In considering the treatment of tuberculous and the arrest or absorption of tubercio, we must, in a measure, disregard the varied and special symptoms of the disease, and sustain and support the general strength. The nutritive functions being primarily at fault demand the closest attention, and whatever conduces to their healthy performance holds out the best means of controlling morbid action, and of averting the tendency to local congestion and exadation; for when these changes have occurred, the molecules or granular matter of which the exadation consists are liable to lead to softening and disintegration.

As cases of tuberculosis differ like other forms of consumptive disease, remedies of a varied character are required. In some instances in children the temperature of the body is high at su early stage of the illness, and the circulation is accelerated; there is thirst and derangement of the gastro-intestinal tract, and food is not digested, even if there is any remnant of appetite left. Antiphlogistic measures and cooling drinks to subdue this febrile excitoment are absolutely required. We have seen how frequently broughitis or pneamonia is associated with this condition, and when they are met with, salines and disphoretics are required before supporting measures can be safely employed. If the cough is hard and tearing, and there is soreness and constriction of the chest, a tonic and stimulating plan would aggravate the condition. When moist sounds in the chest have succeeded to dry rhonchus or tubular breathing, we may commence the system of treatment which modern practice has sanctioned, and give col-

Surriton in Realth and Discore, 1876, p. 83.

hver oil and mild tonics during the daytime. In the evening, when febrile symptoms are chiefly observed, citrate of potash and the alkaline carbonates will abate the excitement, and soon enable us to give quinine safely in small or large doses so as to check the febrile exacerbations. For children I am in the habit of giving a grain of quinine in powder half an hour before going to bed, and sponging the body lightly with topid water, if hot and dry, or with cold water if the temperature is disposed to rise rapidly.

Cod-liver oil is the most effectual remedy of all others in the management of this disorder, and may be given when febrile excitement has not departed. Dr. Williams says: "Cod-liver oil, when taken into the system in sufficient quantities, and for a sufficient length of time, acts as a nutrient, not only adding to the fat of the body, but also promoting the healthy growth of the protoplasm and the tissue-cells, and in some way, as an alterative, counteracting the merbid tendency to the proliferation of the decaying cells of pus, tubercle, and kindred exceptantic and aplastic matters."

When the oil is pale and pure it seldom causes muses or disturbs the functions of the liver. I prefer giving it after a meal in a little orange wine or with a small quantity of milk, which, however, does not always agree. Dr. Williams gives it with a mild acid or aromatic bitter-he gives the nitrie, hydrochloric, sulphurie, or phosphorie, according to the special circumstances of each case, and I can speak most favorably of the combination. I have been in the habit of giving the hydrochloric acid before the meal, and the col afterwards. In weakness of the stomach, with a tendency to retching and nanson, the Joth or Jod of a grain of strychula is given by Dr. Williams with each dose of oil. But it must have come within the experience of every one that coddiver all, when long continued, is upt to disagree with the stomach, and to cause biliary derangement, particularly if the diet is not carefully regulated. Here it must be suspended for a time, and an alterative and alkaline treatment employed till digestion is restored to a healthy state. In the winter season of the year cod-liver oil is an indispensable remedy, and may be continued for months together. There is a preparation called the compound phosphorated cod-liver oil, which I have found useful in the strumous

^{*} Op. cit., 1871, p. 022.

I Prepared by Sayony and Moore, New Bond Street. A fleid drucket contains one grain of indian, wen grains of bremine, and one ferticth of a grain of phosphorus.

diseases of children. But, however combined, the daily me of the oil has superseded every remedy that has hitlerto been proposed, and there is not a physician in this country or abroad, who is not convinced of its efficacy, both in prolonging life and in caring disease.

The hypophosphites of lime and soda, with strychnia, iron, and quinire, form an excellent combination, with which I am well satisfied in these cases, and in all states of general debility and nervous exhaustion.

Whilst we are giving astringents to check diarrhea, and sein tives to relieve cough, we are diminishing the strongth and appear tite, and the disease meanwhile advances. The best means of relieving these symptoms is to increase the general strength, by supplying the system with fatty elements in a form that can be easily assimilated. We have found this remedy in cod-liver all. The molecular fluid of the chyle consists of fatty particles, from which the blood and tissues of the body are formed, and if chylification is imperfect or tardy, the blood is watery and albuminous, and thus exudation is favored. Physiology never exposed a greater therapeutic error than when it showed the danger of treating low leflammatory exudation by depressing the rital powers so that its molecules were incapable of passing through these transformations which lead to growth and elimination. By an opposite mode of treatment deprayed autrition is restored, the respiratory organs are stimulated to active exertion, and the tissues attract from a better quality of blood the necessary elements for the support of the body.

In the case of an infant, if the mother is delicate, or comes of a consumptive stock, and cannot suckle her child, a healthy surse should be procured. Older children who exhibit a tendency to tuberculosis should wear flamed next the skin; the diet should be plain and nutritious, consisting of eggs and milk, and ment twice

a day if the child can digest it,

Quinino, by improving the strength and appetite, and iron, by altering the quality of the blood, are two most valuable remedies when the digestive functions have been brought into a proper state, and there is no risk of renewing inflammation in the pulmonary organs. If there is any degree of febrile excitement or cough, it is preferable to omit the iron till it is reduced, and direct the treatment to special symptoms. The effect of quinine in asserts

tuber-vulous cases is very remarkable in controlling the remissions and exacerbations of the fever; it is the most valuable remedy we possess, and in every case of oscillating temperature which I have treated it has been followed by a fall. Where the fever has not so quickly yielded, the lung has shown evidence of stone change, in the shape of small and localized pneumonia, or gastro-hepatic disorder, or there has been cause to suspect real tuberculosis. Cod-liver oil should always be given in the daytime, when the temperature is normal, and quinine in the evening, before the rise is expected. The benefits derived from change of air and embathing are too obvious to need illustration.

When we encounter phthisis in the first or incipient stage, we should aim at improving the general health by placing the patient under the most favorable circumstances for controlling inflammation and promoting the absorption of any tubercle or low organized deposit that may have taken place. For this purpose, whatever encourages local inflammation and congestion, such as cold, dimp, and exposure, should be dealt with. Flamed should be wom next the skin, and the feet especially kept warm. Congestion may be relieved by the application night and norning of diluted timeture of loding (one in seven) to that part of the whest which gives evidence of localized mischief. When there is bronthis irritation and cough, a turpentine liniment, or campber liniment containing croton oil, is one of the best and most serviceable applications. The remaining treatment of this stage consists in providing the patient with pure air and a seaside residence, if possible, such as St. Leonard's, Torquay, Ventner, Bournemouth, or Clifton in this country, or the south of France and the healthiest parts of the Mediterranean abroad. Sponging with sea-water, followed by friction, will be necessary, and such exercise as the strength is equal to endure.

Children affected with consumption should not sleep with other children or occupy the same room at night.

In phthisis we have to deal with a low form of cell growth, which has a decided tendency to spread. Our energies then have to be directed to this condition, and this assentially depends upon the improvement of tissue nutrition, for these two things are requisite: first, the agreet of all outgoings which impoverish the system; and second, to improve the assimilation. To attain the first object it is necessary to agreet the nightsweats, and to hold

in check the diarrhosa. Where both exist, sulphate of copper is most useful, and it is often well to give opinm with it. Where there are profese sweats without distribute, belladomn is our shortanchor. According to Heidenhain, belladonna paralyzas the secretory nerve-endings of the andoriparous glands. Children tolerate beliadonns much better than adults, and no serious toxic symptoms need be appreheaded from anything like medicinal doses. It is well to prescribe belladonna in the form of its active agent atropia. As sulphate of atropia, beliadonna can be given in prorise doses, while it has the great advantage of being tameless. Children will tolerate doses communing with gr /th at bedrime, while doses of gr 4,th three times a day never give real cause for anxiety. The failure of belladonus may usually be traced to insufficiency of the doss. In the very rare cases where belladonna falla, oxide of zine with hyoseyamus may be resorted to. Gallic acid, quinine, dilute sulphuric acid, and the fincture of perchloride of fron are all useful remedies to arrest night perspiration. When any of these remedies, and fall doses of belladouna. fail to arrest the nightsweats, then it becomes necessary to sponge the child over with tollet vinegar, or with warm vinegar and capsicum (a teaspoonful of cayenne pepper to the half pint of vinegar diluted with water; about half an bour before the motal time when the sweats become profuse. The arrest of the loss of bloodsalts in the sweats usually leads to improvement in the appetite. The next point then is to improve the assimilative process. It is use less to give tonics and luematics as long as the digostion is out of order. If the tongue be foul, an occasional dose of calonel at bedtime, with a little phosphoric acid and a vegetable bitter three times a day, is indicated. When the tongue is raw or hare, or denuded of epithelium, bismuth with a little alkali is called for. When the appetite has returned and the digestive organs are fairly working, then, and not till then, tonics and hounties may be prescribed.

Dr. McCall Anderson has recorded two interesting cases of artice phthisis in young subjects, which yielded to the treatment employed, the temperature falling in both instances from 105° to the normal point in the course of a few days; the explous riles disappearing, the appetite returning, and loss of flesh and strength being rapidly regained. To control the high fever he applied to the abdomes folded pieces of flannel wrong out of load water for half an hour at a time, and gave quinine, opium, and digitalis internally. For the profuse perspiration he had recourse to the sebentaneous injection of gr., 14th of sulphate of atropia every night, which entirely arrested it after the second night. When the injection was conitted the swelling returned, and again subsided on resuming it. Nourishment in the shape of brandy, soup, and lead milk were given every hour."

In the shape of medicines we must be guided in a great measure by the pulmonary condition. If it is tolerably quiescent, the syrap of the iodide of iron, the syrap of phosphate of iron, and the mineral acids will be demanded. Cod-liver oil or malt extract if there is wasting. When the disease has passed into the second stage or that of suppuration, we must outpley such remedies as relieve cough and facilitate expectoration. If the patient is very week, and the lung has broken down, the accumulation of matter in a cavity is attended with most distressing symptoms,—weight and pain in the chest, gasping respiration, incessant cough, wandering, sleeplessness, and excitement.

The inhalation of carbolic acid by means of the spray (1 in 40) will sometimes relieve this, but it often fails, and then it is necessary to resort to an emetic of sulphate of zine,—about ten grains in a tablespoonful of water, followed by a little warm water, will effect this purpose. In a girl 14 years of age, under my care in 1869, with a large cavity in the upper lobe of the left lung, I found this act remarkably well. It never occasioned beenoptysis, of which there is a dread, but embled the poor child to throw off a large quantity of pus from her chest, followed by great comfort and relief in breathing.

Cough is a prominent symptom of phthicis, which always calls for attention. If it is bosse and moderate, and the child can obtain a fair amount of rest, special remedies to check it are hardly needed; if given they are apt to impair the appetite, to derange digestion, and to lock up secretion. There are similar drawbacks to bromide of potassium, though to a less extent, but if the child is kept awake at night it becomes exhausted, and then the simplest remedies should be first tried, as poppy and squill.† If the cough

On Acute Pichicis (Galloging Consumption), The Louise, 1877, vol. h.pp. 413-425.
 Formula 74:

is hard and violent, with scarcely any expectoration, and there is venifting also, morphia and hydrocyanic acid may be needed; when it comes on to convulsive paroxysms, belladeana, stramoulum, etc. If the tongue is forced, the threat irritable, and there is any amount of bronchitis, chlorate of potash, with syrup of tolu and morphia may be required,† and if the expectoration is difficult, incommands or squill may be given, according to circumstances.) Where there is great sleeplessness, hydrate of chloral, with bromide of potassium in syrup of tolu or squill, may sometimes be given with advantage. Where the respiration is accelerated because the lung-space is infringed upon, the administration of distinctly depressing remedies is fraught with danger of paralyzing the respiratory efforts.

In the treatment of hemophysis we must be guided by the amount of blood lost. If small in quantity, perfect rest should be maintained, ice to suck, and the avoidance of all stimulants may be enough to check it, but if there be any considerable loss, and the long is breaking down, or there is a cavity, some styptic remedy must be employed at regular intervals. Dr. C. J. B. Williams speaks highly of gallic acid with soid tartrate of potash. Tannic acid and gallic acid combined, acetate of lead, ergot, and tineture of perchloride of iron are all useful in special cases. The dist should consist of milk, cold beaf twa, broth, etc. It is important

to keep the bowels well open, and for this purpose sulphate of magseria and sulphuric acid, in infusion of roses, is a good formula. When the hemoptysis has ceased, cod-liver oil and other tonics can be resumed.

Distrikes is another complication of phthisis tending to produce great exhaustion and emaciation. When persistent it may depend upon alceration of the small investine. It is a symptom that must be combated at once by remedies of a suitable character. If the tengue is coated, and there is impaired digestion or unbealthy faces, a few grains of gray powder with rhubarb will be needed, and when the secretions are corrected, one of the diarrhora formule will be useful." These containing bismuth, logurous, krasurin, sulphate of copper and opium, acetate of lead, etc., are the last. Opiate encounts must be had recourse to in severe cases, and fencutation and poultiess may be required if there is abdominal pain and tenderness. The diet should consist of rice, milk, arrow-root, etc.

The hypophosphites of fime and soda are highly spoken of by some authorities. They are especially recommended by Dr. Thorowgood. In many cases under his care "decided and unmistakable good came of their administration, and that too when other welldevised means of cure had proved useless." He gives instances in which "nightsweats" and fever gradually disappeared, and moist sounds in the lungs ceased under their administration. In a few cases cavities contracted and became drier. Some of the patients when seen months afterwards appeared well. Dr. Thorougood advises the hypophospite of auto when there is a tendency to gastric irritation, and the linse-salt in cases of diarrhosa. To the former a few grains of blearbonate of soda may often be advantageously added. Where there is slight congestion at the apex of the lung, and there is crackling or clicking, it may be used, but if dyspepsin or bronchitis from recent cold is present, it should be temporarily exchanged for other remedies. In the early or incipient stage, when there is localized dulness, with harsh or tubular breathing, or even when crackling announces that the lung is congested or giving way, he has found them of great value. He gives the hypophosphite of sods or lime, in infusion of calumba, three

^{*} See Chap. XV, On Diarriera.

¹ On Consumption and its Treatment by the Hypophosphites, 3d edit, 1880.

p. 35%.

times a slay." It may be combined with bark! or some of the preparations of iron.; The hypophosphites are well speken of in combination with end liver oil, phosphoric acid, quinine and glysterin by Dr. C. J. B. Williams.; "Of all the tenies for strengthening the stomach and preventing muses, with the oil, strychnia is by far the best; and as it has no beating property, its addition to the compound orange infusion supplies the most elegant and effectual form of adsauer that I have yet devised."] I have long been in the habit of prescribing strychnia in these cases with the best advantage.

Is children, owing to the thinness of the clust-walls, the impulse of the heart is diffused over a larger space than in adults; but unfrequently a part of the right ventricle may be detected besting immediately under the left costal cartilages, close to the stemum. The apex may also be seen, as well as felt, in the normal position. When the intercostal spaces are depressed, and the ribe prominent at their attachment to the sternam, the partial outline of the heart becomes all the more distinct. The shape of the chest, whether natural, rickety, or pigeon-breasted, will influence the area of percussion dulness, and the extent of the cardine movement perceptible beneath the thoraxic parietes.

The size of the heart does not increase with absolute regularity in childhood, for Rilliet and Earthez have shown that between the age of fifteen mouths and five years and a half, its circumference remains nearly the same, increasing slowly afterwards

until paberty.

PUNCTIONAL DISEASE OF THE HEADT.

Polystotics.—We understand by polyitation a frequent and to multious action of the heart, not usually accompanied by organic disease, though it is sometimes present in valvular affections. On placing the hand over the cardine region, a sublen and violent thumping movement is approachle, and the heart's action can be seen beneath the chest-walls. The sounds are exaggerated, and there is sometimes a soft bruit which vanishes when the organ resumes its ordinary tranquility. When the disorder is well pronounced, there is considerable constitutional excitement, quick pulse, headache, and a tendency to syncope. The female sex is more liable to it than the male. As growth proceeds, and the health remains delicate, sontinued polpitation of the heart may induce hypertrophy or dilatation.

The course of this functional disorder are the nervous temperament, running after neals, violent exercise, mental emotion, anger, fear, etc. It is often witnessed among choraic children, and those reduced by chronic or lingering disease, loss of blood, dyspepila, and pulmonary affections. In Graves's disease exopathalmia the anamic condition is accompanied by pulpitation of the heart and

throbbing of the arteries.

The diagnosis mainly rests on the absence of the signs of organic disease and the frequency of the pulse, followed by steadings and

regularity as the attack subsides.

The treatment consists in the removal of the cause, if this can be done, and the improvement of the digestive and nervous functions. Where there is dyspepsia, an alkali with hydrocyanic neid will calm the excitement, and afterwards the ammenio-citrate of iron, with a drop or two of liquor strychnic, according to ago, may be given with advantage. The emplastrum bellulouse may be applied over the eardine region if there he pain there. When the symptoms persist, the main hope of relief depends on an improved state of the blood and attention to hygienic rules.

Spaceps or Jointing is occasionally observed in children of neryour constitution. A peculiar sensation is first experienced of fixeness and so imming before the eyes, and singing noises in the pars. Then the face and lips become puls, the skin clanmy, and the pulse at the wrist so weak that it is harely perceptible. The patient if unsupported falls to the ground, and the breathing is hardly distinguishable. This alarms friends and bystanders, for the pallor of the face is deathlike, the muscles are relaxed, and the extremities are cold. By and by, if the recumbent porture is nmintained, a few deep sighs are drawn, and as respiration is established the natural color of the face returns. Mild cases do aid tast over a few seconds and the pulse is only slow and weak; but severe cases continue for some minutes, and the patient no scener shows sigm of rallying than, in attempting to stand up, the syncope returns at once, the cyclids quiver, and drops of sweat stand upon the forehead.

The cruses are less of blood, or even the sight of it in some aerrous constitutions, profuse diarrhous, extreme fatigue, serore pain, and affections of the heart. Soliden shock, or even excite-

ment, are also capable of producing the symptoms.

Treatment.—The recombent posture should be maintained, and a current of fresh air be admitted; anamonia to the neutrils, sprinking cold water over the face, becoming all dress, and friction of the limbs. When the patient can swallow, a little brandy and water, or a draught containing ammonia with spirit of chlorotom, should be given. If the vapor of ammonia be applied to the nostrile, it should be done with care.

Newcoast Affections.—These consist of a neurosis of the cardine gargin, inducing functional disturbance in the heart's action. This neurosis is, I believe, a very common disorder among delitate children. When they ery on slight provocation, and are testless and excitable, a careful examination of the heart and circulation will often throw light upon an obscure set of symptoms. Have examiner fully entered into this subject.* The complaint

Neuronal Affections of the Healet in Children, Practitioner, Sept., 1875.

is observed in weak and delicate children, and in those who suffer from chorea or nervous states resembling it. Children who are born prematurely, and who are badly reared and neglected during the first year of life, are liable to it as they approach sexen or eight years of age, particularly if the strain of school life is put upon them too early. General debility from any cause, such as ansemia and loss of blood, by disturbing the equanimity of the nervous system, will cause perverted nerve action. It may follow whooping cough, chronic enlargement of the tonsils, or chronic pneumonia. The offspring of nervous or insane parents are also subject to it.

The systetoes are, pulpitation of the heart, followed by faintness and exhaustion. If the hand he placed over the cardiac region, a thumping, violent movement is communicated to it, accompanied by irregularity or intermission of the pulse. This symptom is always a sign of imperfect nuncular action through the quality of the blood and the unstable condition of the pervous system. Seep is unrefrushing, and restless or noisy; dreaming is common; and the princ often contains phosphates.

The trochest which I have almost invariably found successful consists in the employment of rest and tonics, good food, coldingr oil, and warm clothing. Steel wine and arsenic (Form 26, quining, the syrup of phosphate of iron, the formus dialysatus (dialyzed iron), and Parrish's chemical food, are valuable remedies in particular cases; but I place the greatest confidence in a conbination of iron, digitalis, and stryclmin. If there is excitement, and sleep cannot be obtained, iron may be combined with the bramids of potassium.

One eyes on Symportunat Deceases or the Heart.

Perionditis.—Two varieties of pericarditis are commonly described, the sente and chronic. Inflammation of the pericardium consists in the first instance of distension of the expillaries, and secondly of effusion of serum or lymph exuding from them; and in some cases, as absorption of the fluid proceeds, it ends in the gluing of the two surfaces of the pericardium together. The character of the exudation is in a great measure dependent upon the constitutional condition of the patient.

The general symptoms of neute pericurditis are more or less pain in the precordial region at the situation of the apex, or at the lower end of the sternam; it may strike through the thorax to the scapula, or extend down the left arm to the ellow and wrist. The pain in most acute cases is of a sharp, lancingting character, and is aggravated at each shallow inspiration, or movement of the patient. He cannot turn on his side, or bear the elightest pressure over the thorax; even the weight of the bedelothes is opprossive. The pain in pericarditia, when accompanied by articuhe rhousatism, may be owing to an affection of the museles; and in one case which came under my mare, where the physical signs were not conclusive, the cervical muscles were considerably implirated, and the patient could not move his head from side to side in the slightest degree." Sometimes the pain is of a dull, aching, continuous character, or it is too slight to attract notice; in many instances it is absent altogether, and the physician might overlook pericardial mischief, if the anxions and slarmed expression of the patient did not invite a close impaction of the thoracic contents. This anxiety of expression, moreover, in frequently noticeable before there are any reliable physical signs to indicate a boson in the pericurdium. Pulpitation and irregular action of the heart are by no means infrequently added to the pain as the disease proceeds.

Plearing is sometimes associated with pericarditis, and may even originate the latter affection by extension. Endocarditis is frequently present, the two diseases being in close relationship with one another, and arising from precisely the same causes.

Pericarditis sometimes commences with rigors succeeded by forer, and a full, hard, and frequent pulse,—in some cases it is small, unequal, or irregular. As efficient takes place there are dyspaces, harried respiration, great restlessness, and insomnia. The commencement of the disorder may be marked by heat of skin, but this is soon bathed in perspiration, and the face becomes

^{* &}quot;But pain is far from bring a constant indication of percentrists, and M. Bouthard has found in so often alread, that he supplies it, when present to the constance of plantes, and Dr. Hope, although he does not agree with M. Bouthard in this spinion, put state as the possit of his extractive experience, that in the great majority of cases of pericentris the pain was either whelly about or was of a mist and contamble bin! "Sample, On Discuss of the Host, 1876, p. 140.

⁷ Dr. Siban meritared that in 31 cm of 62 cose there we gain in the side; in in master the left side, to the right in 5, and in both sides in 4. In 15 cm of the 21, then a planting friction around one heard in the side. On Pericarditis, Reynolds's System of Medicina, vol. in, p. 222.

pinched and intensely auxious. In young children there may be early convulsions, and as exhaustion proceeds, and the circulation is more embarrassed, there is debrium, and abrupt sleep disturbed by dreams. In severe cases, the child has the expression of alarm and dread, he cannot lie easy in any position, and is afraid of being examined or approached. When the disease is about to terminate fatally elamany sweats break out, the face becomes livid, and the error are staring and glassy.

The characteristic auscultatory sign which renders the diagnosis unnistakable is a to-and-fro sound (boult de featureat). This is the earliest sign of pericarditis, which cannot be discovered unless the friction sound is produced. (The late Dr. Hyde Salter, and Dr. George Johnson, of King's College Hospital, insist that the friction-sound is triple "rub-a-dub dubb." There is first the agricular contraction, then the contraction of the restricte, and lastly the dilutation of the ventricle in diastole.) This sound depends on the position of the exulation, if it cover the nuclei there is decidedly auricular friction, such as Dr. Johnson has described; if the lymph cover the centricle only, the sound is simply to and fro. This sound is caused by the rubbing together of the inflamed surfaces of the pericardium, and a very goal initation of it may be obtained by applying one and of a sterhoscope against the ear, and the other against the palm of the hand. The forefinger of one hand is then rubbed lunkwards and forwards acress the hand so applied, when the peculiar friction sound will be transmitted through the sterhoscope to the ear. The marner caused by the attrition of the inflamed surface of the heart and pericardium closely resembles this. It varies accessarily in the neter and intensity according to the consistence of the clined lymph; if moderately thick it has a creaking character, like new leather (trail de cuie), or a rasp-file-like sound (from its regel-When effusion takes place to such an extent that the two surfaces do not approximate, the marmur is generally, though not investably, lost, and the heart's sounds are distant or nonffied. When the friction nurnour and the cardiac sounds both disappear, we may expect that the quantity of exadation is considerable. Important as this marmur is in a diagnostic point of view, we should set greatly if we supposed that its presence was necessary to the existence of pericarditis, for a large effusion may have taken place at a very early stage of the disease, and the sound will be about

till the effusion has become partially absorbed. The absence of the marmur altogether is quite compatible with severe inflammation. of the pericardium. An endocardial murmur is also frequently heard (proving the haplication of the endocardium) in the space midway between the left nipple and the sternum, which soon extends over the whole pre-contial region. The exocardial muriour is distinguished by the superficial character of the sound, and by its limitation to the cardine region, as well as by its change of character, and its temporary disappearance when the effusion is great. If the offusion is perrely liquid it may be absorbed, but if it be more fibrinous and solid, the pericardium is thickened, and the opposed surfaces may become adherent. When exudation has taken place, the physical signs of pericarditis are increased dulness over the percondial region, according to the extent of the effusion, or rather the area of diminished resonance is not increased, unless the efficien is considerable. The percussion dulness occurs chiefly at the less of the heart, where the pericardium is loose and most easily distensible. It may extend upwards to the second rib, and transversely from the right side of the storoun to the line of the left nipple: When the pericardial sae is distended to any extent the cardine apex is pushed upwards and outwards. In the case of a boy, 7 years of age, with endocarditis and pericardial effusion, the spex-beat was in the fourth interspace, an inch and a half external to the nipple-line, and the endocardial marmor was very loud towards the left axillary region. In cases of this kind the beart's sounds are often feelde, distant, and indistinct.

Pericurditis may terminate in complete restoration to health where the effusion is serous and watery; but if lymph or solid thrinous matter is thrown out into the pericardial suc it is likely to end in adhesion of the opposed surfaces, and lead to those general and physical signs recognized under the name of chemic ptrimulities. It is often accompanied by endocarditis.

Disgressis and Propassis.—The diagnosis is easy enough if the case is well marked, and the effusion is serous and moderate in quantity. In such cases as these the patient may make a complete recovery, and be none the worse for the seizure. If the affusion is thick and fibrinous, as we have just seen, it may cause roughening, or adhesion of the surfaces. Defirium is an important diagnostic symptom, and when it occurs early in the discuse it may lead to the false impression that the brain is the sent of the

malady. When delirium supervenes in the course of rhemutic fever, it would be a culpable error not to investigate the condition of the heart carefully at every visit, exposing the patient, however, as little as possible. Orthopness is also an important diagnostic sign. The disease is very fatal in weak and stramous children.

Morbid Anchory.—There is an effusion of sorum, assertines of a transparent lemon-color, or of a reddish tinge, or there is pus in the pericardium with congulable lymph, and adhesion between the two membranes. The two surfaces, when torn asander at this stage, present a honeycombed or tripelike appearance. The white spots, so commonly found on the surface of the heart after death, have been shown by Sir James Paget to arise from previous inflammation.

Course.—As an idiopathic affection, neutropericarditis is extremely rare, yet it does now and then occur, and may escape dotection in the absence of pain about the heart; as an accompariment of neutrophysical results in a very common. "In 5 cases of pericarditis, in 2 of neutro, and in 4 of chronic endocarditis, and in 2 more in which both the pericardium and endocardium were involved—making a total of 13 out of 39 cases, or exactly 1 in 3, rheumatism was certainly known, or alleged on good grounds, to have been the starting-point of the mischief." "Of pericarditis not in alliance with rheumatism, Corvinart gives five cases, and it was complicated with inflammation of other parts in all of them except one, and in this it was caused by a severe blow upon the region of the heart." It may arise from the extension of plearity or promisents, or is associated with recal disease, chorea, measles, or scarlation... Andral has met with it as a complication of small-

^{*} West, On the Disease of Infincy and Childhood, 1979, p. 481.

^{*} In 2 cases of particulative, in 2 of acute, and 1 of choose endoquelitie, or 6 out of 20 instances, the eliseuse of the limit was travel to an article of smalet-fever. The cooline symptoms did not manifest themselves in the acute stage of the affection, lest during the process of desquantism. They were necessignaled by forer and wassers, which, however, did not should mere perfectly of the face and extremities, and it the two instances of perimedicia, both of which run a channel course, deeply case so so the consequence of the heart disease."—Red.

¹ Dr. P. M. Latkum, On Discours of the Beart, New Syd. Soc., 1870, vol. 5, p. 2D.

I "Pericarditie is not frequent in case-of neare Bright's discuss from excitations in the young since it cally occurred in I in £8, or 7 per cent, of the patients under 16 years of age."—Bibook, On Pericarditis, Brynolde's Spreas of Medicine, and in, p. 466.

pox, and in the last stages of tubercular disease of the lungs with vaniers, and with chronic asthma and bronchial congestion. A case in which the pericardium was greatly inflamed, and contained an abundance of turbid yellow scram and lymph, is recorded by Dr. Dyce Duckworth. The child was only eight months old, and the disease appeared to follow on enlargement of the bronchial and mosenteric glands. After death no tubercle was found in the pericardium or brain, but it was general in the pleure, lungs, liver, and spicen."

Transpart.-The objects to be missed at are to reduce the inflammation and to favor the absorption of the effused finid. Leeches may be applied to the cardiac region in strong subjects, and there can be no question of their service where the pain is very acute and the pulse is frequent and hard, but venesection is never necesmry in children, however robust they may be, because reduction of the strength has to be feared, especially as the complaint frequently follows rhoumatism, when the constitution, already low, will not bear further depression, and the blood in many instances is poor and aqueous. A strong mustard poultice is about the best application; its action is quick, it can be obtained at a moment's notice, and when the child complains of the smarting it may occusion, it can be removed at once. In onsex of acute pericunlitia accompanying rheumatic fever in children, I have found these poulties act most beneficially, quickly relieving the precordial distress and unessiness, and I believe controlling the effusion. The clast should be covered with cotton-wool immediately the positive is removed.

The next remedy of service is counter-irritation. I should not bestate to employ a blister whilst the skin is reddened from the rubefacient effects of the mustard. The surface should be painted over with strong blistering fluid, and the chest protected afterwards with cotton-wool. I have never known it do any harm, but the late Dr. Sibson was opposed to blistering, on the ground that it inflicted local injury, tainted the blood by increasing its fibrin, and prolonged the inflammation. He strongly advocated "the application of chloroform over the seat of suffering combined with belladonna liniment, sprinkled on cotton-wool, and towered with oiled silk."† After the action of the blister, an ointment composed of equal parts of savin and mercurial oint-

^{*} Path Transmittion, 1975, vol. mart, p. 246.

ment should be spread on list and applied to the preconlial region. Another excellent application, after the blister has risen, is a combination of mercurial cintment and powdered opins (5) ad 5) recommended many years ago by Dr. Boale.

Hot fomentations are unsatisfactory, because they necessitate exposure of the patient's chest during their coupleyment, and it is doubtful whether they can be borne hot enough to be of any benefit. Then there is the danger of getting a cold or chill, which ought to be guarded against, and so likely is this to happen that, if the case goes on satisfactorily, it is a great mistake to institute frequent stethoscopic examinations of the chest.

Mercury may be given as an aperiont, but not with the view of fulfilling any special indications, and in rhounatic cases it requires great caution. If inflammatory fever runs high, and there is thirst, elevation of temperature, and scanty, turbed urins, then a general antiphlogistic treatment may be carried out, and aperients, directics, altrate and bicarbonate of potash will be required. Even aconite is semetimes useful if the skin lacks moisture, and quinte may be given advantageously in small doses if the temperature is disposed to run high and there are indications of exhaustion.

Option should be employed if there is much pain, as the continuance of it further reduces the strength of the patient, it diministes the cardiac contractions, and controls the hurried circulation; but if the heart gets feeble, the respiration hurried, and the countenance at all livid, then stimulants, in the form of wine or brandy, ammonia, and other will be required.

Chronic pericondits is usually a sequel of an acute attack of rheumatic fever, and is not frequent in children. The chief symptoms are pain in the region of the heart, and inability to lie on the left side, or with the shoulders low. The changes produced in the pericardium where the acute attack has not ended in recolution, are thickening or adhesion of the pericardial surfaces, and effusion of lymph or pas. In consequence of this change the action of the heart is embarrassed, and the nuscular structure of its walls becomes hypertrophicd. When adhesion takes place the action of the heart is rolling or tumbling, and it can be observed over a large space; the apex is seen beating in the epigastrium, which is retracted. With these changes the face is often dusky and anxious, and if with the acute pericardial attacks the culocarding has been also involved, we may have evidences of valvular diseaso.

The transact consists in meeting the symptoms that arise, by Misters to the chest, active saling aperients to relieve the oppressed circulation, and antirheumatic remedies, as bron, quinine, and isdide of retassium.

Hydropericardium.-Pericardial effusion may be the rouls of arote or chronic pericarditis. The physical signs are a gradual increase in the transverse dulness just below the base of the beart, and displacement of the lungs. The dulness may extend across the thorax from the right nipple to the line of the left axilla, and w high up as the top of the eternum. In all effusions into the pericardium, however small or large, dulness extending upwards is the surest diagnostic sign from cardiac hypertrophy.

The amount of offusion by separating the heart from the chestwall causes its impulse to be weak, and bulging of the precordia may ensue. The liver, spleen, and disphragm are depressed. Adherent pericardium lends to dilatation and hypertrophy of the beart.

The symptoms in the case of a lad aged 18, who came under my notice in 1861, were as follows: The patient was suffering from racumstic fever. On the fifth day of the attack, acute pericarditie came on, and four days later there were all the symptoms of extensive pericardial effusion. The patient had to be propped up in hed from the severity of the dyspassa, and he could not lie down for a moment without threatening suffication. The pulse, throughout small, became fluttering, and for some hours imperceptible at the wrist; the skin was bathed in awent, low mottering delirima was frequent, and the patient's life was despaired of. The dulness extended nearly across the sternum from one sipple to the other, and as high as the second rib. The heart's notice could not be detected, but there was no palitable prominence of the precordial region. The patient recovered without any after bad effects, either local or constitutional

The treatment consists in giving aperients and dimetics. Blisters and counter-irritants should be applied to the chest. When there is no chance of the effusion becoming absorbed, an aspirator should be passed through the fifth intercestal space, and some of the fluid drawn off.

An interesting case of pericardial offusion is recorded by Dr.

Barlow, in a boy six years of age. "Twice the pericardium was tapped by the aspirator, and twice the abdomen, with marked relief, and without any bad offects from the operation. The child was feverish throughout, and neither the fever nor the considerable moties could be satisfactorily explained during life, but after death these were found to be due to tubercular peritonitis."

The purely passive form of efficient from electroction to the circulation presents the same symptoms, and the treatment is also similar.

Endo arditio.—This disease consists in inflammation of the ends cardima or lining membrane of the heart, and is frequently associated with pericarditis as a consequence of acute rhenometica. It is most common in the latter affection, but it may arise from exposure to cold, be developed in the course of severe chores, or scarlet fever, or measles, or small-pex. Bright's disease may induce a chronic form.

The general symptoms are a sense of discomfort and unexiness over the cardiac region, auxiety of expression, flushed countemace, and a tendency to syncope. Pain is not always present unless there is pericarditis or plearist, and if auscultation were not practice! carefully the disease might be overlooked. Still, in a few instances pain is severe, and increased on the slightest pressure or movement, so that the weight of the bedelothes is intolerable. There is restlesoness, hot skin, thirst, and fever, followed by perspiration, which is often profuse as the disease advances; the pulse soon becomes quick, feeble, or intermittent, and the breathing is hurried and abdominal. As the disease progresses the lips become livid, the eye is dim, and the face is dull and heavy, or pale and shrunken. Wandering at night, and even delirium and convulsions are among the symptoms. Bronehial congestion, or pulmonary engorgement is apt to ensue from increasing debility, and to failure of the circulation through the lungs.

The physical signs are those indicating mischief at the sortic and mitral orifices, as mentioned under calvular affections; there is usually a soft bruit at the apex with the systole, but the symptoms depend on the valves which are affected, and these are generally on the left side of the heart. The disease may terminate tatally from exhaustion and cerebral symptoms, or, if the

^{*} Us a case of Personalist Efficies, in which Personants was perturned, Proticiones, 1873, vol. a), p. 265.

acute stage be passed over, no traces of the disease may remain. In most severe cases valvular changes ensue, leading to packering of the valves and impairment of their functions, with ultimate obstruction of the circulation and general dropsy. A portion of coagula may be detached from the curtain of the inflamed valve and carried into the general circulation, causing embolism.

In endocarditis as the accompaniment of rheumatic fever there is an inflammation of the liming membrane of the heart. Efficient of lymph into the structure of the valves (solved valvelinis) ensures, which finally becomes converted into a fibrous structure, the shordse tendiness are involved, so that they undergo contraction, and the valves become tied down or puckered up together, which either narrows the mitral orifice (witral structs) or the opening is so with that when the ventricle contracts regurgitation is produced (witral regurgitation). The mitral valve at each ventricular contraction has to sustain much greater pressure than the nortic valve, which has only to bear the force of the returning blood against it.

Treatment.-This should in some measure depend upon the disease with which the cardiac affection is complicated, and seeing that it may arise in the course of acute rheumatism or scarlet fever, it will be important to modify the treatment accordingly. The treatment is really that of pericarditis, with which it is often associated, but there is this difference, endocarditis spendily toads to exhaustion, and is not so amenable to active agents as venescotion and counterirritation. The patient should remain in bed for a length of time after the sente stage has passed over, so that exritement may be diminished, and the effects of strain should be kept off the injured valves by lowering the blood pressure as far as possible. For such purpose chloral hydrate is indicated. This is dwell upon by Dr. Milner Fothergill, in a lecture, in the Modacol Tince and Gazette, Sept., 1878. "This fact, then, is accurtained and confirmed by experience, viz., that the damage done to the endocardium by rheumatic inflammation may alobe for four or tive years without producing any concious detriment to the health or well-being of the patient, or (as far as we have the means of judging) any farther injury to the structure of the heart. And It is a most important and consolatory fact. But in other instances other results immediately follow. When after its departure acute ricomatism leaves the endocardial murmur behind it, which, though known only to the physician, is the sure sign of injury done to the endocardiam, it leaves it attended from the beginning by other symptoms, which the patient is sufficiently conscious of, and these are directly referable to the heart. They consist of pale petation, and some pains, and some dysposa, which are not constantly present, but only under hodily exertion and mental excitement. The child who has had the prescordial marmur ever since it suffered a certain rhoumatic attack, is just the same child as it was before, except that it cannot join in any pastime requiring rapid movement; for then its heart pulpitates, it leses its breath, and is obliged to sit down. Men too are just the same men as they were before, only perhaps they cannot run upstairs without panting and hurry, and they constantly find themselves obliged to restrain their hodily efforts within certain limits, and to beware of mental excitement, for fear of pulpitation and dyspaces. These conditions too may remain for years without either augmentation or abatement. The murmur is never absent, but the pulpitation and dyspaces are never present except as the immediate effect of a certain amount of bedily exertion or mental excitement."+

Myscarditis or inflammation of the heart's substance is generally found in connection with endocarditis or pericarditis, but the moreular structure of the heart may be affected just as the muscles are in subscute or chronic rheamatism, without any inflammation whatever. Myscarditis occurs also in scarlet fever and in typicil fever. After some fatal cases of endocarditis, the walls of the beart have been found to be thickened, and abscores of variable size have been discovered in the muscular structure of the organ. Such changes sometimes occur in death from pyremin, scarlet fever, and some other forms of blood-poisoning. If polpitation and violent pains in the cardiac region come on during rheumatism, and the pain extends through the shoulder, or passes down the arm, the disease may be suspected. The complaint being obscure in its manifestations, the treatment must be regulated in accordance with the most argent symptoms and the cause in operation, if it can be discovered.

Ulcrotter Endocarditis —This disorder superficially resembles the form of endocarditis, frequent in rhequestic subjects, where minute regula form around sudocardial vegetations, and becoming detached, produce embolism in the cerebral and other arteries. But in alternative endocarditis the blood is previously poisoned by

Dr. F. M. Larbern, On Discuss of the Heart, New Syd. Soc., 1976, vol. 1, p. 378.

some specific affection, as small-pox, pyremia, diphtheria, etc., and congula of infected blood form around the cardine valves. Portions of these clots becoming detacked, produce embolism of an infertive character over and above their purely mechanical effects. The disease attacks only persons of had constitution.

For much of the description now about to be given, I am indebted to an interesting feature by Dr. Cayley, on a case of - Elegative or infesting endorarditis simulating typhoid feece in a loy

aged wine years,"h

The discuse is to be distinguished anatomically by a large number of embolisms in the miliary form. The emboli in ordimry endocarditis are lodged in the middle cerebral artery, produring harmorrhage and softening of the corpus striatum and optic thaland, followed by hemiplegia. In alterative endocarditis they are deposited in the pin mater of the homispheres, and do not necessarily produce any cerebral lesion. The intestine is frequently the seat of embolt in this form of endocarditis, and in both varieties the kidneys and speen are the most someon scats of ombolism. The endocarditis of acute rhenmatism may occasionally assume this variety, and it may even supervens on chrome valvalar Managen, F

The general symptoms sometimes resemble ordinary pyremin; there are rigors, high fever of a remittent or intermittent type, and local suppurations. In other cases they resemble typhoid lever, as in the case recorded by Dr. Cayley.

In the typhoid form there are rigors and vomiting, often sweat-

by Willia and Moxen, 1975, p. 475.

Medical Times and Genetic, November 18th, 1977, p. 589.

A come of a boy, et. 14, terminated fatally, through repeare of the heart, almost inmediately after admission lette keepind. A year previously he had an attack of these make Series, and show then had been being flesh, and softend from dyopour on exertion. A formight below admission he had some pain in the cheet, constant dyspeson, and general matrice. When admitted there was a thrill, a slowler number over the serie values, and a systellic manner at the upon. " He sublimly become inscrible, finded in the face, and begun to strongle, and then term it deadly pair and died." A pot contemporarion for all and that "the periourillum was full of computed blood, which had flowed from a very small prifice in a suc bring between the norm and pair money sole, and which was foliated by the posterolos of the part lying at the last of the minut volve, in which destructive informatory observing had produced the balon "- St. George's Hops, Kep., 1874-70, p. 387.

^{1 &}quot;The assempt weight of the spleen in ten case. If alcorable endoughtle counting in 1967-70 was 25 year, they were afterior more or less soft and policy. Very rarely the splices reaches exect to double the latter weight in andisondate." Port, Analogy,

lag, and irregular febrile exacerbations. There are also brown tongers, sordes on the teeth, and delirium passing into coma. The urine is often bloody and albeminous.

Auscultation discovers the signs of valualar obstruction, the tearmers varying according to the orifices affected and the progross of the observation.

The disease tends to a fatal termination, and is not controlled by treatment.

VALVULAR DISEASES OF THE HEART.

The general symptoms of valvular disease of the heart may be thus briefly stated. The blood is either impeded in its passage through the organ, or it regurgitates from debet in the closure of the valves, and this leads to hypertrophy with congestion of the lungs and other organs, followed by dropsy. The symptoms vary a good deal, and in children, even when the valvular condition and hypertrophy appear to be about equal, the constitution suffers differently. This arises from the conservative process of hypertrophy, which, for a long time, keeps in cheek the symptoms; but, by and by, the heart laboring to ounty its overplus, fails, and congestion of the venous system follows. Then casne burried respiration, dysponen, pain in the region of the heart or pulpitation, anxiety of expression, paller or suffusion of the face, inability to walk upstairs, and the impossibility of resting in the recumbent position. The symptoms are increased by indigestion or mental emotion. The valves on the for side of the beart are far more prone to disease than those on the right. When the latter are affected it has been attributed to fetal endocarditis.

The constitutional symptoms in these cases are liable to considerable variation. Some children who have all the physical signs of a severely damaged valve, as the consequence of rheumatic endocarditis, experience no breathlessness and scarcely say other discomfort. They may go on for menths or years with very little complaint. I have more than once known the heart entirely overlooked in these cases, and the symptoms of impaired health ascribed to weakness and general debility. But later on the symptoms of obstruction to the circulation begin to be unsifest, and there are cough, congestion of the lungs, and hurried breathing. In prolonged cases the liver and digestive regass

become deranged, the features are swelled, and ordena of the extremities supervene.

Discuss of the mostle polices is so rare in childhood that it might be passed over annoticed. But, since it does now and then occur-In children, it is well to call attention to this lesion. When the nortic arifice is narrowed or constricted (north skeruthon -north) station), the blood is impeded in its passage from the left rentricle. Over the midsternum, but more especially over the second right costal eartilage, and in the course of the norta and carotide, a soft systelic marmor, corresponding in time with the pulse, is heard, dissinishing in intensity towards the apex. A systelle thrill is often felt over the cardino region, at the right bace, with heaving impulse. There is usually great hypertrophy of the left sensticle. If the heart's action is weak, and the narrowing of the prifice smooth, the murmur may not be easily detected. When the mirrowing is great the pulse is small and forthe, but this will in some degree depend upon the amount of hypertrophypersent, which modifies its character. The constitutional symptoms are pallor of the countenance, and often bendache from cordinal america, owing to the untilled state of the orteries. Unless the mitral valve becomes involved, so as to allow of regurgitation taking place, the pulmonary circulation is not interfered with:

Course.—These are most probably due to chronic valvulitis and to endocarditis after rheumatic fever. When rheumatic endocarditis happens, the inflammation begins in the mitral valve, and then, after involving the ventricular endocardium, seizes upon the acrtic valves. The form assumed by acrtic valvulitis in childhood is certainly that of regargitation; the distortion and mutilation of the valves commences in the free edges, and is usually accompanied by dilatation of the acrtic comes and the actual unlargement of the nortic estions.

When the nortic valves cannot effectually close the orifice on the nortic recoil, the blood stream returns into the centricle, and so for representation is produced. The physical signs are a diastolic murnur, hearf at the midsternum, obliterating the second acand, and frequently distinctly and bloom the upon. It may be noft or sugh, weak or load, musical or prolonged. The pulse is sudden tid jerky; it is known as "Corrigan's pulse," collapsing, "like balls of blood shot under the fingers," but there may be considerable regargitation without this being marked, or any visible pelsation in the superficial vessels.

The tendency of the discuss is to produce extreme hypertrophy of the left ventricle, but very rarely any dropsy. The ventricle being always too full of blood, undergoes comparative hypertrophy, and containing blood in diastole, dilatation is added to hypertrophy.

Dr De Havilland Hall afforded me an opportunity of seeing a patient of his, a boy ten years of age, who was the subject of aortic regurgitation. Six weeks before he came under observation he had complained of pains in his kness and first, and had been confined to bed one week. When seen he was suffering from weakness and giddiness, and some shortness of breath on exertion. On examination, he was found to have a soft acetic disc tolic nursur, heard londest over the third right interspace close to the sternum, and conducted along the sternum to the apex. The impose was greatly diffused, but most marked in the fifth interspace in the nipple-line. There was visible pulsation in the brachial arteries.

Course.—This offection may possibly be congenital. It may also follow chronic changes, violent strains, and endocarditis offer rhounactism in obstructive disease.

Disease of the right anticulo ventricular wishes (trinuspid transpirafive) is care, and murmurs are uncommon in this situation, except In long-standing cases of mitral disease, in which the right side of the heart has become weakened, and there is obstruction to the pulmomary circulation. "Mitral stenosis is the most frequent cause of serious tricuspol regurgitation, and the earlier in life the stenosis occurs, the more rapidly, as a rule, the tricuspid regargitation follows, and the more serious the prognosis." The physical signs are increased procordial dulness to the right of the sternum, at the level of the fourth rib, and epigastric pulsation. the ventricle being seen and felt between the ensiform cartilage and receding ribs in the left hypochondrium. Owing to the accumulation of blood in the right ventricle from congestion of the lungs, it becomes enlarged and dilated. As it encreaches on the position of the left ventricle, and lies in front of it, the apex > pushed away from the chest-wall, and the impulse is extransly

[&]quot; Boliour, op. cit., p. 151,

weak or counct be felt at all. A mormor usually accompanies the erstele, and is more audible over the lower part of the stermust, or ensiform cartilige. I say usually, because the murmor is altogether absent in some cases, and in others it cannot be detected, though the other signs of trionspid incompetency are all present. Accentuations of the pulmonary second sound should be looked for, and weakness of the sortic second. The increased autline can often be distinguished readily enough in children whose chest-walls are thin, and the left lobe of the liver may receive an impulse, while at the same time the liver is not unfreanually enlarged. This condition is often attended with overfulness of the cerrical veins, because the right anniels is overdistended, and in fact the right side of the heart altogether undergoes passive dilatation. The trionspid being insufficient, each contraction of the right wentricle drives luckwards the blood into the right anticle and the veins in communication with it. The wavy puleation in the external jugular veins is an indication of considerable tricuspid regurgitation, but if the orifice is only slightly contracted, than the valve may act efficiently, and the pulsation in the vein be alsesst. Congestion of the intestinal veins, scanty urine, and even homorrhoids, are sometimes present. In a boy, agod cieven years, under my care in 1877 for mitral and tricospid disease, relena and anasarea of the lower extremities came on a month bufors death.

When the cardiac enlargement exists to the same extent in two separate cases, we may have in one case regular bowels and normal extremities with the power to be down and assume any position; whilst in another case there are severe and continuous congestive headache, enlarged veins in the neck, and pulmonary suggestive headache, enlarged veins in the neck, and pulmonary suggestive headache, enlarged veins in the neck, and pulmonary suggestive. This depends upon the amount of injury the valve has austained. If the trienspid orifice is only partially constricted, and there is no defect in the valves, the venous circulation is partially congested; for it should be held in mind that a marmur in this cituation, like a mitral regurgitant murmur, may be simply the expression of great debility.

A systolic nearmer heard most distinctly over the pulmonary trifice is generally due to accomia, or to pressure by consolidated lung. When organic it is almost always congenital.

Disease of the left assessed easternable (settral) take, causing regargitation from the ventricle into the suricle, is the most com-

mon form of cardiac disease to be met with. It is avidenced by a murmur, diastolic in time, and unlike that of mitral stenosis is not caused by the contraction of the auricle. It is very such more frequent in girls than hoys. In these cases there is enlargement of the left ventricle, and the agex-lent is below and external to the nipple; it often occupies a larger space than in health, except when it strikes directly behind a rib, and then it is not detected so readily. The impulse is considerable and heaving, and if the hand be placed over the precordial region, there is an appreciable thrill. Over the spex is a bruit accompanying the systole, partially obscuring the first sound, and diminishing, or even disappearing at the base, if only elight; but if load or intense, it may almost obliterate the second sound at the arex, and be detected over the whole precontial region. The narmar is synchronous with the pulse, and owing to the lood being carried back into the left nuriele, can be bound in the left axilla, at the angle of the scapula on the same side, and at the spiral column. The pulmonary second sound is generally intensified This murrour (boot ste south) is not and bellows-like in recent cases, where possibly the deposit on the valve has become highly organized, but in more advanced cases it is rough and grating. and resembles the sawing of wood. The peculiar vibratory motion (purring tramor-fivinissement motion) occasionally found in disease of the mitral crifice is essentially connected with obstructive, and rarely if ever with mitral regargitant disease. Cough, congestion of the lungs, quick breathing, and a small contracted pulse, are common in these cases.

A load spex murmar in mitral disease is compatible with fair strength and growth, and may be present without impairing the functions of the heart. In such cases there is probably a mere roughening of the surface of the valves, or even a vegetation, which does not permit any of the blood in the ventricle to flow back through the mitral orifice, yet a systolic spex-brait may be present and regurgitation take place with a competent mitral valve. "In fact, the mitral valve may be perfectly free from disease, and the suricule-ventricular opening perfectly natural and undilated, and yet regurgitation may and often does take place." In anomia and chlorosis, a venous murnour may sometimes be heard over the mitral area, accompanied with accentus-

[&]quot; Discous of the Heart, Ballion, 1876, p. 102.

tion of the palmonary second sound, as in true mitral constriction and regargitation, but unassociated with any valvular lesion. There are other cases in which the physical signs are the same, but graver mischief has been done, and the right side of the heart and lungs suffer in time. Children so affected are small, dwarfed, and stunted, and liable to die of dropsy at puberty. They rarely get over the pubertal changes.

Disease of the left serious contrictor or after (statustics disease), covering contraction of the orifice (seited struction and obstruction is the blood for too the west-ide. In this disease congestion of the longs, beneatyses, or pulmonary bemorrhage may case. The effects on the circulation are much the same as in the former case. Chronic breachitis, pacamonia, and urgent despute, general venous congestion, and answers much be looked for. After a time the contamised pulmonary circulation affects the right side of the heart, and its cavities become enlarged; there is increased duliness to the right side of the sterrum, and the right ventricle may be seen and filt between the ensiferm cartilage and the receding ribs to the left bypechondrium in long-standing cases.

Some cases of mitral constriction are supposed to be of congenttal origin, and they continue for years without causing any sign of heart mischief.

The pathognomonic physical sign of obstructive disease of the mitral valve is a presystolic nouronn (aurirular agardic), and when once heard there can exist no doubt as to its significance. The nurseer is produced as the current of blood in its natural passage through the heart encounters resistance at the contracted valvular orifice; the valves being converted into a curtain with a slit in it (the fullow-hole materal), or into a fingerfike cone projecting into the watricle. The bruit immediately precedes the first sound of the leart and carotid pulse; it is prosystolic in character, and is coiscident in time with the contraction of the suricles, and not that of the ventricles. It would serve no practical purpose to enter into the rexed question concerning the exact time during the heart's revolutions at which this murmur is produced, but I would just notice a remark by Dr. Andrew to the effect that it occurs at the latter part of the diastole and seems to be continuous with the first sound, from which it is difficult to distinguish an interval." It is a short and rough murmur, and obliterates the second sound

^{*} On Proposalle Marriers at the Henry's Aper, St. Barth, Hosp. Rep., vol. 200, p. L.

at the apex, but intensifies it at the base. Accentuation of the pulmonary second sound is one of the most constant conditions of mitral stenosia. Its loudness, like all other cardiac marmurs, depends upon the condition of the blood and the size of the aperture, and the force of the heart's action; but why it should disappear from time to time whilst the constriction remains unaltered, is at present unexplained. A cardine thrill (diastolic) is usually present, and the left ventricle is contracted and its walls thin, according to Niemoyer," but Dr. Balfour remarks: "as we never have mitral stems is without regargitation, some degree of hypertrophy of the left ventricle is almost always present, etc."? The left agricle is dilated and hypertrophics, and the right side of the heart also. The pulse is occasionally regular, but often weak, rapid, and irregular. Mitral obstruction and regurgitation may exist together ! The marrour of mitral stenois is heard at the left apex and inslining towards the right spex; whilst a regurgitant normur is carried towards the axilla, or behind from the left nipple to the merial line at the back. It is heard over a less area than that of regargitation. It is generally, but certainly not invariably, limited to the mitral area, "that is, within a circle of about an inch, doarribed round the point where the apex impinges as a centre." An attack of pulmonary catarrh, with elevation of temperature, will often render the murmur softer and more diffused.

The excess which induce valvular diseases of the heart in childdren are acute rheumatism, chronic albuminumia, choren, and the

⁵ Franciski Melicine, 1875, vol. 1, p. 252.

t Diseases of the Heart, 1876, p. 153.

f. A gird at II of rickety constitution, was admitted have the Sammum Hopkel, under try case, in November, 1973, with symptoms of mittal structur. There are no history of riccambination or clearer, the discase being probably conqueited. Two years presently also had a severe usage, and three up a good deed of blood. The large gave some proof of hypersonia and congestion. The furnt's action was thought and subject to the sixth interquee below, a little constant to the nipple large and in the direction of the opiquetrion. There was now hypersonially and distant on the lark side of the large. There was no thrill, but a very distant programmer, limited to the axes of the sarries upon of a pastering concrete character, falling in force bowards in termination, like a sensed dying away in the distance. It was well considered by the latters Replace Chart, as Dy. Batter has pointed out topolity, p. 116). A hander and different marriar was heard posteriorly, and antherwisely line also in diminished force over the right cheet and back; it was syrectic see had all the characters of a mirral regressional marriar. The pulse averaged 10; it was proble, we gething, weak, and wavy, but regulat.

A Balfort, ep cit, p. 183.

specific fevers, especially scarlet fever; indeed, any circumstance which will sex up perbearditis and endocarditis may lead to dilatation or contraction of the sardiac orifices, and to adhesion and rigidity of the valves which grand them. Dr. Hayden considers the poison of searlet fever as most in frequency to that of rhoumatism in producing heart discuss. "Many of the most formidable examples of valvular lesion that I have met with ored their originto scarlatina. The patients are generally children, and rarely survive the second period of life. The complication is usually declared in the second week of the fever, but on researchly in the first week, or the stage of desymmation." Endocarditis is set up as we have already seen (xide Endocarditis), and the valves, more especially the mitral valve, become involved in structural change. Of thirteen cases of beart disease associated with scorletion, which came under Dr. Sansom's care, there were three cases of periconditie; one case was uncomplicated, and two cases were complicated with endoundill's (notral regurgitation). There were ten cases of endocarditis, inducing mitral regurgitation in eight cases, one case of dilatation of left and right cavities, mitral stonosis in one case, mitral stense s and regurgitation one case. In six cases of heart disease associated with measles, there was pericarditis with endaand the (mitral regurgitation) in one case; codecoditie inducing mitral regargitation in three cases. In one case hypertrophy and dilatation; in one case trionspid insufficiency; in one case mitral stenosis; in one case mitral stenosis and regurgitation.)

Dr. Dyes Duckworth has collected eighty cases of mitral stanesis, of which only seventeen were males; the oldest patient was 63, the youngest (a girl) 14. He arrives at the conclusion that two-thirds of the cases had a rheumatic origin, and that fright, strain, and other injuries are to be enumerated among the list of causes, or rather, as the writer observes, the valve not being healthy, these special causes were enough to aggravate the condition which already existed. Slow degenerative changes in the mitral valve leading to stenosis are, I think, rightly considered not uncommon.; In the case of two girls affected with mitral stetosis, who came under my notice, aged respectively 13 and 17,

Discuss of the Hues and Aura, 1875, p. 315.

² On the Enology of Mitral Stemois, St. Burth. Hosp. Rep., vol. 201, p. 263.

there was no history of rhousantism, nor of any illness that could account for this grave cardine condition. Of the above cightly cases, six only were traceable to choren. Uf sixty-one fittal cases of shores mentioned by Dr. Hilton Fagge, there were only two in which all the valves of the heart were perfectly healthy."

Treatment of Valendar Discours, -This is at last but montisfietore. We cannot restore the lajured valve in its integrity; but use can fester the growth of hypertrophy, and in some formulacases even restore the ventricular chamber to its normal size. The symptoms which arise as a consequence of these organic changes are best relieved by rest and the avoidance of exercise and excitement. By maintaining the general strength and guarding against local congestions and inflammatory attacks, we may often succeed in giving a fair share of health and confort to children; while warm clothing (particularly cotton-wool or fame) worn over the chest), nutritions food, and active sperients will tend to keep in check some of the worst symptoms, as dropsy, when they show themselves. If congestion of the lungs, or bronchitis occur, squill, carbonate of animonia, belladenna, stryclnia, and other stimulating expectorants and singuisms, will be indiestect.

When the heart is getting weak and quick in mitral disease, and there is a tendency to dilatation of the right cavities, tinciure of digitalis, administered in gradually increasing doses, will improve the tone and fulness of the pulse-beat, reduce the frequency of the heart's action, and cause the overdistended eavities to contract more vigorously on their contents. Instead, therefore of blood accumulating in the least during diastole, a larger quantity is expelled at each contraction of the ventricle. Digitalis has been said to increase the discharge of urine, but there is noun doubt about this so long as low arterial tension remains unaffected. I carefully measured the quantity passed in two cases of mitral regurgitation in children with dilatation of the right ventricle, set in neither was there any appreciable difference in the amount passed, nor any change in his quality. They were in no way inproved by the drug. Traube first noticed that the fall of the pulse-rate, and the rise of arterial tension during the conjugmost of digitalis, are attended with an increased amount of urine

Brysold's System of Medicine, Director of the Value of the Heath-well in p. 169.

In nearly all the cases in which I have given digitalls for the beart affections of children, I have combined it with iron, and frequently with strychnia also. Iron improves the quality of the Bood and the muscular power of the heart. Digitalis is of most value in simple dilatation from debility in the cardiac muscle, and in tota forms of mitral disease, where weakness and irregularity of the pulse are present. It may be given with advantage in dilatation with hypertrophy, but not in the latter form of heart affection alone. If nausea, headache, or unsteadiness of pulse should come on during the employment of digitalis, the drug should be intermitted for awhile.

In cortain rickety children, with thornoic deformity and twisting of the zorta, hypertrophy of the left contricle is early develtood (Rokitansky), and in some cases even valvular discuse (Bitton Fagge).

Heart cough is common in adults in the failing stages of heart disease, and is usually found in children at any stage. It is the result of congestion of the pulmonic circulation; it is aggravated by substices, such as puregorie, and even by brounds of potassium; it is effectually relieved by cardine tenies like digitalis combined with iron, and when very troublesome it is well to put the patient to bull with complete rost for a week or two.

Hypertrophy and Dilutation.—Hypertrophy of the heart, which consists of an increase in its muscular tissue, is owing to the greater-effort which the organ makes to overcome the obstruction of blood through its excities.

In children it is noticed as a consequence of valuable disease imperially of mitral obstruction or reguegitation), adherent periturdion, (mphysema of the lungs, and chronic renal disease.

The physical signs are heaving impulse, diffused over a large space, visible to the eye, and raising the head of the listener when the ear is applied to the cardino region. The spex-leaf may be seen and felt between the sixth and seventh ribs, or even lower. The pulse is full and strong in simple hypertrophy, but if accompanied with dilatation, the force of the arterial stream is considerably lessened. The heart's sounds are dull or muffled, and very rarely accompanied by murmur. The area of dulness is introded laterally, and to the left of the sterman when the left ventricle is involved. When pulsaonary employeens is present, the correspondences is masked through the margins of the lungs

overlapping the heart. In rickety subjects the precordial region is sometimes rounded or preminent. When the right ventricle is affected, which is common in long-standing cases, there is appartite pulsation, and the margin of the ventricle can be folt to the left of the ensiform cardiage. When obstruction exists at the mitral orifice (most common in children), the left nuricle becomes exertilled with blood and its cavity enlarged. As the blood scannulates in the pulsacoury circuit, the right ventricle gradually becomes hypertrophicd and dilated, so that one cavity after another is more or less affected. In mitral discuss, the left ventricle may remain stationary or contract in size, whilst the left sarricle is enlarged; the heart is globular or rounded in form, and the apex chiefly consists of the right ventricle.

The constitutional symptoms vary according to the mischief which has produced the hypertrophy. The walls yield and the cavities undergo oblitation when the heart is enfected from over-exertion. The displace the lungs. General dilatation of the cavities is usually seen in fat and feeble adults who have suffered from memorrhagia, chronic bronchitis, or other exhausting illness, but in children it is most frequently the result of mitral regurgitation.

Hypertrophy of the heart, associated with more or less dilutation, is a common attendant on chronic kidney disease. The left ventricle is most frequently involved. It arises from avergrowth of muscle, in consequence of an obstacle in the smaller arteriss and expideries, which the heart is striving to overcome." These resorts become contracted and cause high tension in the vascular system, because the structural change in the kidney prevents the ofinitization of area, and other products of metamorphosed tissue. These accumulate in the blood and lead to thickening of the smaller bloodvessels, hypertrophy, dropoleal effusion, and houseringes.

The grace of signs of sillestries are a frequent, weak, or irregular pulse; the veins of the neck are often prominent when the right side of the heart is affected, and if the case proceeds from had to worse, there is dyspaces, bleated face, anxious counterance, and finally orders or dropsy. The physical signs are a themping action of the heart, if there is much hypertrophy, but if not, those

^{*} See Chap. XXIV, On Chronic Desquaratira Nephritis.

of dilatation may prevail, and then the impulse is weak, short, or transloss. The first sound is feeler and diffused.

The causes of dilutation, pure and simple, are amenda and genemt debility, beonehitis and emphysoma of the langs, but it is usually associated with valvular discusses, as we have seen, and then the symptoms vary according to the orifices affected, and the degree of hypertrophy.

The treatment is that of valvular disease of the heart, with which

both conditions are so closely associated.

With respect to mulformation of the heart, the sepima which divides the ventricles is occasionally deficient, and the two cavities communicate. The foramen evals is also large and open in some cases, or the folds of membrane are not sufficiently developed to close the orifice, so that the blood passes from the right surious into the left acricle. For an interesting account of these various irregularities, the render is referred to Dr. Penceck's excellent work."

With this condition there is often contraction at the orifice of the pulmomery artery, which may be so reduced in size, as barely to admit a quilt. If the contraction is considerable, and the formuse ovale large, the right ventricle is small, and there is largertrophy and dilatation on the left side.

Cycrosis.—The symptoms of this peculiar affection are a blue tint of the skin, tongue, and lips, and a general coldness of the surface. The patient is subject to pulpitation and violent action of the heart, faintness, and syncope; the pulse is feeble and sometimes irregular, and broughitis, congestion of the lungs, heamoptysis, and serons offusions are upt to suvervene, when the disorder is of any considerable duration.

Among the physical signs, the existence of a normar is genstrally to be detected over the point of communication. In the following case there was no bruit.

N. C.—, aged 3, was admitted into the Samuritan Hospital under my care, October 22d, 1877, with well-marked symptoms of tyanosis. The mother attributed the symptoms to the shock of the gunpowder explosion in Regent's Park, but the child had suffered from whosping cough shortly after livth, and at the time of the explosion had a severe cough. On admission, the counterance was deeply congested, and the lips were of a claret hue; the

^{*} On Malformations of the Heart, 2d oils, 1805, p. 107.

swollen eyes stood forward in their seekets, and the cyclids were cedematous; the feet and hands lacked warmth, and presented the same venocity as the face. The child was constantly turning and twisting about in bed to obtain case, and when freiful and irritable tens darkest in color. Sometimes she would lie on her face, sleeping for hours together, and resenting any interference. The pulse was 140, contracted and small; respirations short and shallow. The chest, both in front and behind, was rescant. The bousts were regular; urine, sp. gr. 1018, fair in quantity, pale, slightly clouded, non-albuminous, and of neutral reaction.

No muriour could be heard over any of the heart's orifices, the sounds being distinct throughout the cardine region, as well as posteriorly. The action resembled an excited and pulpitating heart, and was much worse at one time than at mother. The temperature on admission was 100°, at the end of ten days it fell to 98.4°, when the mother took the child out of the hospital. Death took place a month afterwards.

The course are a communication between the suricles, or a single auricle and ventricle, or narrowing of the pulmonary artery, and mitral orifice. Opinious are much divided on the causes which induce this discoloration of surface. The case of a male infatt, nine months old, is recorded by Dr. Cayley, in which the nortic valves were extensively discussed. From birth the child was short of breath, and when first brought for treatment there was dyspara, left no symposis. The cardiac impulse was much increased, and there was a loud systolic murmur over the cardiac region. Before death there was some degree of sysnosia. "On post-mortem examination the left ventricle was found much hypertrophied. The nortic orifice was much constricted, and the valves were covered with large, firmly adherent, fibrous vegetations, evidently of lang standing."s It has been attributed by some authorities to general congertion of the venous system from obstruction at the pointmany orifice (pulsamenty strace); the others to the admixture of

[&]quot; Iran Trues, 1975, vol. 22vi. p. 35.

[†] Dr. Percock showed a sponsor before the Pathelogical Society (Octaber 1865) of stemons of the pulmourry arrays from discussed the values, which he believed to be congested. The bey was 13 years of age, always livid, and seven strong Dyspora and incremed lividity circus on a short time before he was admitted into heaping. "There was a lead double narrows over the pulmourry cartillars, and a distinct shrift." The patient was dropiced and died. After death the right contride our toned dilated and hypertrophics, and the triffer of the pulmourry arrays autrems and found abayed.

vessus with arterial blood; whilst there are those who contond for the presence of ventus blood in the atteries and general circulation, us the true explanation of the liability. It has been stated by Dr. Still that synnosis may exist without the intermixture of the currents of blood, and that intermixture may take place without any cyanosis. M. Valleix does not think that a communication between the right and left cavities of the heart is a certain proof of cyanosis. It is, however, generally regarded as due to smous congestion and the mixture of arterial with venous blood. The latter hypothesis soones the most correct, for, as Dr. Walabetruly remarks, the most intense venous obstruction may exist in the adult without producing cyanoris. Dr. Peacock regards evatoils as due to congestion of the ventus system. Though it would seem difficult to determine the exact condition, it is not improbably due in some instances to fulness of the remous radicles, and imperfect semtion.

The proposes is most unsatisfactory. The child may die from syrope, or in a fit of coughing and urpost dyspoon from rangestion of the lungs. Instances are mentioned of adult life being attained, "and in one case, recorded by Louis, the age of fiftyseron was reached."

The treatment consists in rest, pure air, and warmth, careful diet, and attention to the digestive organs.

Scuple Messagitis .- Inflammation of the pin arachnoid is nor known as biptomeningitis. The grachhold and pin mater are in such close rolation to each other that it is not always possible to separate them in the morbid changes to which they are liable moler the inflammatory process; neither are we clinically able to describe, with anything approaching exactness, the symptons of inflammation of the membrane apart from inflammation of the cerebral mass itself: "There is no symptom which, during life, could help to distinguish between inflammation affecting the pix mater and inflammation involving the arachnood alone; and as the treatment in either case would be the same, there would be to practical solvantage gained by such distinction." I do not happen to have more with an instance in which the arachnoid menleans has been inflamed and the pia mater not implicated also pair arsoholis); but cases of the kind are recorded in the history of medicine. If the meningitis has been due to tranmatic causes, then the dam mater is involved in the inflammatory process, and a circumscribed ratch of fibrinous expolation or purabet matter may be seen lying upon it. According to Dr. Greenfield, the pix mater is "primarily and thirdly affected" in secondary meningitis,

A Strayle Montagatio, by J. Sperson Brandell, M.D., Baynelch's System of Medicare, et al., p. 297.

or that arising from contaminated blood, whilst "in traumatic meningitis, the dura mater and arachnoid, or the arachnoid itself, is chiefly involved."

"Durastrachnitis, or puckymeningitis, with its effusion between the arachneid surfaces, is an affection intimately connected with disease of the dura mater, and arises from some external cause; whilst the effusion beneath the arachneid, and immediately in connection with the cerebral substance, has its cause within, and constitutes the idiopathic inflammation of the nombranes. In policary idiopathic meningitis, the effusion, be it lymph or pus, is proved out from the pia mater, a structure which consists of a nost rich piexus of vessels, held together by delicate areolar tissue, following all the inequalities of the convolutions, and lying beneath the lared surface of the viscoral arachneid membrane, with which it is connected by fine filaments, forming a delicate texture that crosses the subarachnoid surface."

The scatterical appearances of simple or acute movingitis, then, are great by personia and vascularity of the pia mater and arachnoil, with the effusion of scrum, or the exudation of lymph, or screptraient matter, or pus itself, in patches of variable size, octurying the subarachnoidean space, dipping into the salei, and obliterating the convolutions.

When the dura mater is removed, the membrane beneath is seen to be vascular and congested, either generally, which is very rare, or in patches over the superficial portion of the hemispheres. It sanctimes presents a glistening whitish look, and is thin and almost transporent; or it is thicker, with an opalescent or faint unlky appearance. Sometimes it is greenish-jellow, and does not exceed the thickness of a line. When the membrane is removed, distanted ressels and infimmatory explation may be seen dipping down between the convolutions and depressions of the brain; but in teamy cases the congestion is not more than may be observed in children who have died of fever or some other acute disease in which the brain has only shown signs of exhaustion during life. (komionally the under surface of the amchaoid is covered with exulation, or false membrane, which contracts adhesions between it and the brain. This transparent fluid may also be seen in the vestricles, rarying from one draches to an onnes or more; and an

^{*} St. Th., and Harman Beyond, coll. visit, 1877. It 1884.

¹ Pathological Australy, by Wilks and Maron, 1870, p. 308.

opaque, gelatinous fluid may, in some cases, he observed at the base of the brain. Puralent matter is an eccasional but rare occarrence. In some cases that have set in suddenly and terminated in a few days, the vessels of the scalp will be found distended with blood, and the brain and membranes turgid; lymph may be seen scattered over the convolutions, so as scarly to coneral them, and the substance of the brain is generally soft and vascular, whilst the scrum in the ventricles is turbid or purulent. Some of these cases have received the name of "water-stoke" by Gölis.

Simple leptomeningitis generally selects the convexity of the cerebral hemispheres, whilst the base of the brain is the chown mut of the exudation in the tubercular variety. The convexity of the anterior lobe is more frequently affected, but the exulation may run along the surface of the brain posteriorly, and attack the inferior aspect of the cerebellum and the medulla oblongata. It may involve the upper portion of the spinal cord, and he surounded by a considerable quantity of turbid serum. The lateral portions of the lemispheres, and still more rarely the under surface, are more affected in this form of meningitis; at the same time the extent and locality of the inflammation are variable, and the symptoms are much more acute in some cases than in others. The disease has many points which resemble tubereniar meningitie; but it is not so common, and is loss frequently met with in children thus that affection. It occurs occasi nally among infants, but is very rare after the age of two years. I have seen two cases in single young women; one seventeen, the other twenty years of age. Exprouse to cold and privation seemed to be the cause in the younger case, and debility and amenia after typhoid fever the cause of the other. Simple or idiopathic meningitis, not arising from local irritation or injury, tumors or other morbid growths in the beain or its numbranes, must be considered as a rare disease.

Consist—Injuries of the head may set up meningitis in children.

A joung lady, aged 11, previously in good health, told for mether that she had had a fall on returning from school. She than att a good dinner, but was sick in the evening; had severe healache and fever next day; the pain began on the byt side of the bod, extending in a few hours to the opposite side, and along the upper part of the spine. She died rather suddenly little more than forty-eight hours after the fall. The arachnoid was dry and

rather opaque, with numerous yellowish-white ratches between it and the pla mater. The vessels on the surface of the brain were much distended. No disease of either tympanum or petrons hone could be detected. Dr. Crisp was "disposed to think that the fall, which might have been more severe than at first supercool," was the cause of the moningitis, which was remarkably localized les the brain-substance was healthy) and unusually rapid." Meningitis may ensue from concussion of the brain at once, or follow it after weeks or even mouths, if the child has attempted to exert its brain too soon after apparent recovery. Immederate reading, extremes of heat and cold, checked craptions about the head and face, are also to be enumerated among the causes. A frequent muse is the extension of the inflammation from the internal ear, Cities interns is probably often the unsuspected cause of meningais, for it is not necessary that external discharge or obvious caries of the bone should occur, a far slighter degree of inflammoution sufficing to set up the disease." the Sometimes the symptoms of ctitis distinctly precede those of meningitis. Sometimes the moningitis sets in without any precedent symptoms of otitis; and when this is the case, sometimes the symptoms of otitis show themselves in the course of the meningitis; sometimes the otitis is latent and undiscoverable throughout."; But long standing otorrhou, which has led to disease of the petrous portion of the temporal bone, the exanthematous fevers, and especially scarlet fever, are causes of the affection. If in a child so suffering, delirium, high fever, convulsions, or come result, we may suspect the supervertion of meningitis. Eryslacius probably induces the complaint in a similar massier. A case is recorded of fatal meningitis in a child which was induced by the rough measures which were employed to extract a stone from the cur. I It may occur so an spidence in conjunction with inflammation of the spinal meninges, constituting cerebrospinal meningitis. The action of the poison a directed to the meninges, just as the blood infection of septi-

Meigs and Popper, Diamers of Children, ja 509.

caunia, albuminuria, syphills, rheumatism, or the specific fevers, may originate measingitis or pleurisy, or any other form of serous inflammation. Simple meningitis may follow whooping-cough and bronchopseumonia.

Simple morangitis, when it does not result from tranmatic causes, must not be considered beyond the possibility of recovery. The exudation poured out under the inflammatory process slowly contracts into a fibrous structure, and the pin morer into a whitish firm membrane, adherent to the brain on one side and the under surface of the amcharod on the other. This disease may begin with acute and active symptoms, and in the course of two days attains its climax. Strong and healthy children are more frequently attacked than those who inherit delicate constitutions. Some cases set in slowly and insidiously, and the most careful and experienced practitioner may be deceived as to what is about to happen. Tale difference in the symptoms is chiefly owing to the circumstance that the disease may come on primarily, or in consequence of other discuses. In the latter case there may be nothing but great depression of the rital powers, and eventually paralysis, while where it is primary, it is usually ushered in by rigors and heat, with high temperature, and a quick pulse.

One reason why meningitis is not to be overlooked in these cases arises from the absence of the whole train of symptoms which are said to belong to that state. The symptoms are more developed in some cases than in others; but it must not be supposed that we are not dealing with meningitis because a few of the symptoms only are present, and have not successful one another in my regular order. Each case has its separate commencement and class of symptoms-it may have a tardy and obscure beginning. of days and even weeks, or be sudden and heree in its development. If a child with febrile symptoms has benduche, nunsea, and voniting, and brings up life, we must be careful lest we direct our attention to the stomach, and neglect the head. If the bolly is soft, and free from tenderness and distension, the hourely sostive, and the teogue clean, the signs are of still more ominous omet-If they vanish for a time and recur again, and there has been to indiscretion or irregularity of living to account for it, we must exercise caution in the expression of an opinion. There are cases of cerebral disease to be met with in young children, preceded by such insidious indications of failing health that the possibility of brain affection is overlooked altogether, and the symptoms are either attributed to fever, to some pulmonary disorder, or they are so obscure that the practitioner is anable to form any diagnosis. At this early period it is doubtful whether the symptoms are due to any mortod change in the membranes or cerebral thane. It is indisputable that some of the symptoms which spring from ecomtrie sources of irritation, propagate an indirect influence to the brain, and give them the semblance of isming direct from the besin itself. Moreover, any long-continued illness in a badly possished shild exposes him to the danger of cerebral disease, especially if he is the offspring of tubercular or syphilitic parents. Approaching dentition renders him more susceptible through the irritation it excites - a tedious attack of diarrhum still further imporerishes the brain, and reduces the general health. Group, brouchitis, or any other scute disease, will be equally powerful in disturbing the equilibrium of the circulation, and fretting the nervous system till it culminates in an artual outbreak. Watch the out-putient department of any London hospital where there are a fair number of children, and we shall often find that a child who is recovering from diarrhosa, or has an eruption of the scalp, or suffers from general debility, or has been exposed to great heat, and the searching rays of the sun, is suddenly seized with a fit of convulsions, followed by inflammation of the brain-

Specificar.—In most examples of simple meningitis, languor, imusisess, and symptoms of excitement will manifest themselves for some days before the accession of more dangerous symptoms. Severe headache is one of the most constant and percistent symptoms. It may be so acute as to cause the child to utter a pieroing cry. The eyes have a wild and glistening look, the jupils are contracted, and the child shows the light. Strabismus of one or both eyes is sometimes present, the vessels of the conjunctive are injected, and the temporal arteries throb. The pulse is frequent, sharp, and incompressible. It is sometimes slow at the commencement of the illness, but accelerated after food, or any attempt to examine the child. The breathing may be soft and regular at this stage. The child may draw a deep sigh now and then, and more its head about on the pillow as if in surray sleep. The head is bot, and the veins about the temples swollen and dilated in some eases, whilst in others the face presents a palled book, alternating with an occasional flush over the malar

boost and upper portion of the cheeks. Then follow wandering and delirium at night, with intercals of consciousness during the day, to be shortly succeeded by convulsions, or increasing exhaustion and death. The temperature is generally elevated, though it is not always so in the early stages of maningiris. In some cases it runs exceedingly high. It may vary three or four degrees during the day when there are relapses and exacerbations, Thus is the morning it may be normal, and by the sysning reach 103° or even 106°, especially if the case has succeeded scaries fever, oterhous, or pneumonia. The tengue is natural, or white and moist; and thirst is frequently complained of whilst intelligence remains clear. Vomiting, of sympathetic origin, is very often present, and when associated with meningitis is usually accompanied by constipated towels.

Some cases set in with a parexyon of convulsions, especially in very young children, which, according to Andral and Sir Thomas Watson," denote greater certainty of seecheal Inflammation than delirium. But cases so beginning have shown, after death, the brain-substance to be free from inflammation altogetier, and as lymph in the arachaoid cavity. Both Andral and Aborerouble have seen bustanees in which loss of speech was the first indication of the illness. In the case of a child, aged three years, whom I attended, the first symptom to direct attention to the brain was the sudden loss of speech, or rather an imperfect gurranal artiralation. This was followed in the course of a few days by headache, pyrexia, and vomiting; quick pulse; plosis and partial hemiplogia, and no amendment in the power of speech. The urine was slightly albaminous. When the little child was asked a simple questionit moved its lips sluggishly, and the tongue performed a positiar rolling motion, but nothing like an articulately prenounced work could be uttered. When names and comiting are the earliest symptoms the infimmation is said by Sir Thomas Watson to have originated in the substance of the brain; when convalidors have attended the outbreak of the symptoms, it has originated in the aracheold or pia mater, and when early and force delirium tre present, the gray portions of the convolutions or superficial parts of the hemispheres are first invaded. This is highly probable, and it accords with my experience that delirium is a striking feature of irritation or excitement of the membranes, whilst convulsions

^{*} Practice of Physic, vol. 1, p. 765, 5th edit., 1557.

are oftener associated with cysts and deepseated tumors, or such changes as occur at the base of the brain in some forms of chronic and tabercular meningitis.

in cases less violent than those I have described, some increase of irritability, slayness of manner, uneasy sleep, headachs and sickness, will on inquiry, in most instances, he found to have preceded as actual outbreak. In young children all these semptoms are common to intestinal derangement, and hence they increase the difficulty of forming a differential diagnosis." Headache and siekness are among the carliest symptoms, inviting our attention to the brain as the organ primarily at fault. If these two symptoms were about we might very naturally overlook the disease. As the discuse advances towards a tatal termination the legathing is inegular and often sighing; it is semetimes so tranquil that it sterns to have suddenly stopped. The expression is bewildered and confused, and the eyes are fixed and staring. The pupils may be of equal wize, even if convulsions and restlessness are present; but if the child becomes unconscious, and there are any symptoms of puralysis, then one or both may become widely dilated and insensitive to light. When countous symptoms occur at a later stage of the illness, the pupils become dilated, or one is more dilated than the other, and there may be squinting and partial plosis. The temperature is at first increased, and in the later stages of the disease lowered, ranging between 94° and 104°.

The condition of the eyes, as revealed by the ophthalmoscope, is referred to in the next chapter, lest I may here quote Dr. Greenfeld's experience: "Optic neuritis is absent in the larger number of cases of neute meningitis of the vertex, whether simple or tulerenlar, if the cases in which there is a tubercular infiltration or tumor, or a coincident basal meningitis are excluded. Where any affection of the eye exists in meningitis of the vertex, it is nece commonly only swelling of the papilla, or choked disk, and only teaches any further stage in the cases of localized meningitis oftenest syphilitie) which run a subscente course."† In a case of aumingitis complicated with coordina, in which after death the membranes were found thick and opaque, the optic nerve was covered with a whitish cloud partially hiding the ressels, and there was optic neuritic from congestion of the vessels along the

See Chap. VIII. On Typical Ferry.
 Sr. Thomas's Haspini Reports, 1877, p. 160.

optic nerves. (Gee, op. cit.) The pulse may now become so mpid that it cannot be counted, and the heart's action may be feeble and tumultuous. The radial pulse is not to be detected at each futtering earlise contraction. Instead of the fierce delirium of the early stage, the shild may now be observed to roll its head from side to side, and there is flushing of one or both checks, as is frequent in the evening paroxysm of typhold fever in young subjects, Add to this catalogue of symptoms the presence of stertor, and indications of gradual effusion going on at the base of the brain. and we complete the description of a hopeless condition. The belly is sunken and retracted, the motions are dark and offensive; and as the disease advances they may be passed in the bed meansciously. In those exceptional cases that recover, signs of improvement either set in early, or the disease does not reach the severe stage I have been describing. It is more chronic and obscure, and does not run on with the relicity of the fatal forms.

Some cases recover, under great care and patience, if the disease has not set in with fleree delirium or convulsions, and the fever is moderate. But death at the ond of a week is the rule. In some cases the disease terminates fatally in less than forty-right hours. The general intelligence is defective in the very few cases I lars seen get well, and the memory and power of attention are inpaired. Whether the brain is ever again able to hear full intel lectual tension is an open question; but morfol anatomy reveals nothing incompatible with it in the case of young and otherwise healthy children. I have met with two cases of recovery from a subscute form of simple meningitis in children in whom the tenperature at no period of the illness exceeded the normal point, though the head became large in both cases from efficien. In one of the cases there was hemiplegia, stralismus, and evacuations wore passed unconsciously. The morbid changes in the brain and membranes must have been nonsnally slow and chronic.

Freehorst—A child suffering from acute meningitis should be seen at least every four or six hours, to watch the effect of the progress of the discuss on the one hand, and the action of the remedies on the other. The principle of treatment is comparatively simple. It should combine two elements. 1. To lower the vascularity in the inflamed part by depressing the circulation and for this end we possess two well-known agents, aconite and taturated antimony. 2. To soothe and calm the excited or inflamed escephalic centres, and this is best attained by the use of io ide of petassium. These agents then may be combined. Chloral hydrate probably produces both of these affects. It must, however, be home in mind that all depressants in children are apt to produce, varying results, even ordinary doses will induce at times an unanticipated degree of prostration, out of all proportion to the dose employed. Careful observation and repeated attention, at comparatively short intervals, are therefore demanded, in order to note if the semedies are exercising too great an effect.

Each one having special and peculiar features, no plan can be laid down as suitable for all. In the neuto and early stages of the disease, mercury is a remedy of undoubted value, and ought to be employed, but only as a purgative to thoroughly empty the bowels, and to insure a free discharge of bile. The bodily powers must be carefully estimated before we resert to it. It is essential that the bowels be kept freely open, and the renal secretion encouraged, as tending to lesson coroleral congestion. The employment of caloned on the plea of preventing exadation is an exploded theory. After this, indide of potassium is the remedy to rely on in noningitis.

The head is to be shared, and cold affusion applied, either by ice in a bindder, with the effect vigorously watched, whilst the delirium is fierce and active, or what is preferable, the ice-cap, as employed at the Samaritan Hospital in cases of surgical fever and cerdeni congestion. At the same time mustard positices may be

applied to the unives of the legs.

Leader have been used, but they are not very satisfactory, and can scarcely be advocated in young children, the loss of blood not being well borne, except in very special cases. The pallor of the face, and frequency of pulse that follow their use, should make us extremely timid of their application; and yet, from the correbul congestion witnessed in some fatal cases, the abstraction of blood appears warrantable. When used they should be applied to the certex, or close behind the cars, where pressure can be readily applied, if the blunding is too active, and there is few of the child being too much blood. They may be employed with greater chance of good than in the tubercular form of the disease, where the will night be appravated. Dr. Wilks is in favor of leaching. He says, "I believe, therefore, that at the present day, if you think a child has neute meningitis setting in, you will have no

better treatment at hand than the application of leeches, and the saline with antimony."

Salines, as chlorate and extrate of potash, are to be recommended when the more soute symptoms are lessening, or the urine is turbid and high-colored. Hydrate of chloral is sometimes useful, and especially brounde of potassium in large doses when a sedative is indicated. The latter remedy will often check the tendency to convulsions (Ringer). Small quantities of milk, and beef ten later on, are fitting forms of nourishment. In the early stages the diel should be low and unstimulating. Cold drinks may be given freely. For the debility and emaciation that result, an ordinary toole treatment, including ammonia, quinine, iron, and strychnia are to be employed.

When come has set in, a blister as the nape of the neck, or behind the cars is advisable, and stimulants, as ammonia, spirit of chloroform, etc., should be given in the place of moreurials and purgatives.

Acute moningitis runs a rapid course in spite of blooding, leeching, and the most active treatment. It may destroy life in twenty four hours, and the patient never recover consciousness from the time of the attack, or it may last some weeks in exceptional cases.

Tubercular Messagitis,-The pin materia the membrane in which the deposition of tubercle takes place in the form of unling granules. According to some pathologists they are not seen on the free surface of the arachnoid, or in any way connected with it; but this to use is a doubtful point, seeing the affinity which tuberile has for serous membranes in other parts of the hody, Unlike its loose investment around the spinal cord, the aradmoid is closely adherent to the pia mater, except where the latter menbrane dips into the convolutions, and the arachnoid stretshes across them. Here the tubercles in cases of meningitis are most abundantly seen, and they are often found in this situation when they cannot be detected in any other. This looks as though the araclmoid had some attraction for the deposit, as the pia mater quits its fellow-membrane at the base of the brain, where its uneven surface admits of the divergence being readily traced. The connective tissue of the araclmoid resembles the delicate structure of the pia mater itself, which is made up of flat membranous cells,

^{*} On Discuss of the Newman System, 1878, p. 157.

connective-tisezo bundles, and clasile fibres, so that where the two membranes are firmly united, it is not possible to say which was the most attractive to the morled change. The amelaoid, thee, having all the characters of a serous membrane, and preseating tubercular deposit at its freest part, seems to be as much a factor in the process as the pia mater. It is important to exercise great care in looking for those small granules lest they excupe. notice; they should be diligently sought for wherever any explation of yellow fibrinous or amorphous matter is found. These miliary granulations may be observed in the Sylvian fossa, and the longitudinal fissure, and in the course of the vessels along the base of the brain to the medula oblongata, especially about the cerobellum, where the eighth and minth pair of nerves may be conrealed by a semi-gelatinous effusion. I have seen the origin of the effectory nerves, the tuber cinereum, loous perforatus, the comminute of the optic nerves, and the anterior half of the pons varolii completely hidden by this exudation. The growths are He size of pins' heads, of a grayleh-rellow, somi-transparent color, and have long since been ascortained not to depend on any inflammatory products, as was formerly supposed. Semetimes they may he observed adherent to the pin mater, where it dips down between the convolutions; but at the base of the brain, where the arachtool owers the cerebellum, they may be detected clustering topetior in the greatest numbers-not, however, that, as far as we know, the number of these tubercular granulations hears any corresponding relation to the extent of inflammation, or the rapidity with which the symptoms are developed. These tubercular growths appear to be in intimate relation with the smallest arteries, on the tides of which they form a distinct projection. They consist chiefly of small cells, a little larger than a blood-corpuscle, and summerous free nuclei. The inflammation associated with these small bodies has no distinctive character from ordinary inflammatory changes. Sometimes caseous and degenerative products are set up, as may be observed in serofulous inflammation; or they undergo similar changes themselves, and lead to effusion of scrum or acroparulent matter in the ventricles, which is one of the com-

* Frey's Histology, by Barker, 1874, p. 200.

[†] For an interesting account of the mirror neatons of samiageal talends, I refer the reader to Joseph and Stercking's Pattalogical Anatomy, by Dr. Payne, 1875, p. 212.

momest consequences of neute hydrocephalus. The choroid plaxes is full and vascular in a few cases, and the walls of the ventricins present a faint pink has. The plaxus may be pale, however, and the surface of the corpus callosum and optic thalami soft and eroded. Tubercular messingitis is not invariably associated with the deposit of tubercle in other parts of the body. Though we should carefully look for tubercular deposit, or some signs of strumous inflammation in the lungs and bronchial glands, yet such are not always found in the most marked cases of tubercle in the meninges; and it is strange that the connection, close as it certainly is, should be set down by many authors as of almost invariable occurrence.

"The distinctive characters of tubercular meningitis are the absence of lymph on the surface of the brain (in this it infora from simple meningitis), a flattening of the homospheres, lymph at the base, tubercles in the pia mater following the course of the vessels, and increased fluid in the ventricles, with softening of their walls. Even if tubercles were not visible to the naked eye, the rest of these characters would at once indicate the nature of the discuse, and the microscope will always find the tubercles along the vessels."

Symptons.—This disease is usually met with in children of first one to seven or eight years of age. Of 48 nmles affected at the Children's Hospital between August, 1862, and March, 1873, 25 were major five years of age; and of 38 females, 23 more under five years of age.† It may happen to children of a few months old; but the ages I have given are the most frequent. When children grow older the image are more likely to be attacked than the brain. As in some other forms of nerve disorder, the child usually exhibits evidence of impuired health for some time before the outleenk of cerebral symptoms. "The disease is less arise than that last mentioned (acute meningitis) generally running a course of three or four weeks, with symptoms less violent." But the symptoms may arise suddenly, and run a fatal course in a few days. There is an absence of minimation and habitual liveliness about the child. It throws its autosements absurptly on one side,

^{*} Wills and Manuel's Pachological Ametony, 1875, p. 212.

¹ Willia and Manous's Pachological Austrany, 1875, p. 220.

as if they fired or annoyed it, and it falls adeep in the daytime. It eries without reason, and quarrels with its companions. It is morese, shy, and timid; and becomes inconsolable if its mother. leaves it or intrusts it to the care of a stranger. It may have been losing flesh, and looking deficate and pallid; but not more than is constantly observed in young children who are otherwise in average health. In this premonitory stage there may be simple irritation or congestion of the brain, and until some inflammation serurs, the shild may go on in this condition for an indefinite period. If these threatening symptoms attract attention they may sometimes be subdued by appropriate treatment, and weeks of careful watching and strict diet may postpone the coming avil; for it is doubtful whether true meningitis ever develops itself suddealy, some obscure symptoms of a local or general nature may have escaped observation. The symptoms that demand reportal totice are vomiting, constitution, alteration of the pulse and respiration, stmbismus, and local or general convulsions and paralysis. In a diagnostic point of view there are several considerations to be analyzed and dwelt open."

Vositing is a frequent symptom, and often steals on institiously. The child takes its food as usual, but rejects it the instant it is swallowed, yet it is willing to eat again immediately afterwards. It may be sick only suce in the day, or oftener; but as the disease advances sickness becomes more frequent, and the stomach will reject plain trater. This form of voniting is unaccompanied by pain or gastric disturbance. Where this symptom has been of some duration the eyes are sunken and have a languid book, whilst the fice is pinched and thin. It may be present in the subscute as well as in the zoute varieties of meningitis, and may, in the former cases, have lasted some considerable time without attracting notion. In the absence of headache it is often everlooked, but having once set in it usually goes on the appetite diminishing manwhile; the helly is flattened and concave, the edges of the mording ribs have a sharp outline, and the intercostal spaces are sunken and retracted. Vomiting, however, is not invariably present, and a case of tabercular meningitis may run its course from beginning to end without this symptom.

Countyation, as in simple encephalitis, is the rule, and a full dose

^{*} The Cognisis from passenceds, pleasing, and typhold force, it gives in the chapins or those subjects;

of aperient medicine is required to move the bowels. The chasnoter of the motions is subject to much change. They are generally dark, or clay-colored, and forid; but they may be healthylocking and only diminished in quantity. Still there may be diarchen, and this circumstance should not beguile us into looking elsewhere for an explanation of the head symptoms. Diarrhus and fever in meningitis are confessedly embarrassing signs, as they are the two characteristic and concomitant symptoms of typhoid fever. As the disease advances the motions may be passed unconsciously.

There is not much thirst in the absence of federile phenomena, except in those cases of tuberculosis in other organs in the body, when the evening temperature runs up to 105° or 107°, and the skin is but and purgent; in the latter stages of uncomplicated moningitis the febrile phenomena are high. As the disease advances and socialitity is biunted, the bindder is upt to become paralyzed, and the orine ammenincal and albuminous. I have seen the bladder distended up to the umbilious, and requiring the use of the catheter. Veget's says he has not found albumen in the urise of these patients; but if it is searched for carefully, we shall detect it frequently in this, as well as in many of the congestive and inflammatory discuses of children. When it is small in amount, and the solids of the urise are sufficiently eliminated, it is of an great import, and does not add to the gravity of the case.

The palse deserves our closest attention in this disease. It is variable in force and frequency; and this fluctuation may be taken to indicate pressure, either from fluid slowly poured out into the ventricles, or from increasing congestion of the cerebral resolution the sarly stage of the disease the pulse may be quickened, but it is usually regular; later on it lessens in frequency, and we have the slow pulse of hydrocephalic disease. It may be slow one hour and quick another, and become rapid or irregular after food, and whilst digestion is proceeding. If that stage of the disease reached when it is fluttering and too rapid to be counted, it is significant of great danger, and the end is not far distant. We cannot infer with anything like accuracy that the state of the pulse or pupils is indicative of effusion or congestion, not can so make out with certainty what changes have occurred in the consistence of the brain.

^{*} Diseases of Children, p. 364, 1675.

The character of the respiration is a nest significant sign. It is similar to what is observed in simple miningitis, irregular or fluttering-hadrouphille sight-tranquil, as if momentarily arrested, then gasping as if death were at hand. This is an indication of servous exhaustion and unsteadiness in the respiratory centre. When the pulse is quick the respiration is also accolerated in many cases; but these functions do not hold the close and orderly reintionship which is generally assigned to them. The temperature may run up to 104" in cases of surgical pyrexia without aux increase of respiration-it may be 101" and the respiration 42and when the temperature reaches 1032 it may fall to 20. So with the impulse, when it has fallen us low as 68 strokes in a minute, the temperature has been known to reach 104°. Some allowance must be made for the difference in this class of cases, since in tubercular meningitis, with increasing renous congestion, the respiratory movements are excited to greater frequency.

Hadrede is a frequent symptom at one or another stage of the disease. I have met with it at the period of invasion, and noticed in one well-marked case how the little boy carried his hand to his head when he was too young to speak. When the pain is puroxysmal, or one day present and another absent, it may be mistaken for according; and in the absence of fever I have had my doubts of its caset nature. When it is continuous or severe, the child will cry out with it, and if old enough will tell you that his head as here.

In geneine meningeal inflammation the muscles of the neck are contracted and the head is thrown back. In states of simple irritation and passive effusion, the muscles are relaxed and the child cannot support his head. When laid down to sleep he will rotate it from side to side and after piercing tries of pain. He has startings and tremors in his restless sleep, and the pupils turn upwards under the half-closed cyclids and reveal the conjunctiva. Squinting may be observed in the early periods of the disease when it is acute, and also, in many slow and chronic cases, long before the brain is suspected of going wrong; but, as a rule, it is a late symptom of the disorder, and is complicated with inequality of the pupils, and the absence of somibility in the conjunctiva, when the finger is passed across the cycliall in sleep.

Hemiplegie and paralysis of one arm and beg are to be noticed as occurring in the latter stages.

The two following cases of tubercular meningitis exemplify some of the leading features of the complaint to which I have referred.

CARLI.—G. C:—, et. 4, was one of two chibiren. The child had sharp features, dark bair, and prominent forebond. Father and mother healthy; no others in family. When brought to Dr. Wynn Williams as an out-patient, May 16th, 1877, it was stated that the child was perfectly well till a fortnight before, and since then she tras faint and could not sat; she was generally hot, and the tongue furred. A mercurial purge and a saline mixture were ordered. On June 2d there were signs of low fever, and quisless was ordered three times a day. On the 9th there was srow diarrhom.

On the 11th, when admitted into the Dorset Street Hospital, the comparature at 1 n.m. was 100.2°; at 5 m.m. 101°; pulse 58; respiration quiet. The child appeared very languist, the toughe was formed, the skin hot, and the bowels costine. A mixture of citrate of potash and sulphage of magnesia was ordered.

On the 12th at 8 a.s. the temperature was 100°, and the leocels had acted twice. At 5 i.s. she could protrude her tengus, and was sensible; temperature 102,2°, pulse 126. S.r.s. she lad a convulsion, and was not sensible afterwards; temperature 102,2°, 12 r.s., temperature 108,6°, breathing heavily and quickly.

13th .- 1.30 a.m. died.

Part-morton Erromination (righter hours after doubt by Mr. A.
Down.—Body generally pale, except some marks of hypostatic
congrection on the back and posterior part of shoulders. The calvariant was adherent to the dura mater. In the anterior portion
of the right hemisphere, at the part corresponding to the posterior
aspect of the frontal hone, two or three of the convolutions at this
part were separated, and a cavity filled with zerous duid was seen
large enough to contain a walnut. There was no put or lymph to
the cavity, but at its base a few enlarged vessels ramifying in the
pla mater. The cavity immediately became apparent when the
armshoold covering it was opened, and this portion of the membrane, unlike the rest, was of a tawny yellowish color, resembling
a weak solution of iodine or wash leather. At the central line of
the longitudinal fissure, at the upper part of the rerebrum, was a
patch of yellow, purplent-booking lymph, the size of a fourpeaug-

piece, and a smaller patch near it. The brain was generally nach congested, especially posteriorly; at the base around the space commissure was a layer of lymph and shreddy tissue, with small dots, common enough in tubercular maningitis. There was a large amount of subarachnood fluid of a pale, scrous, milky color. There were about two concess and a half of scrous fluid in the lateral ventricles.

The unaware was studded with enlarged glands, the average size being that of a small and. The first was generally pulled and studded with tubercles, it extended into the left hypechoodrium, touching the ribs on either side, and there was not a quarter of an uch of healthy liver free from these granulations; the periodesian generally was studded with them, but especially that which covered the diaphragm, where they were seen in large patches, the size of the palm of the hand at the centre, and honeycombed. The spices was thickly covered with them; intestines distended with gas; no prince all distincts. Both lungs were also irregularly studded with tubercles, but not more at the apex than the centre or base. The central lobes were need congested.

CASE II .- A. F., set. 21 years, was admitted into the Sanaritan Hospital under Dr. Wynn Williams, May 21th, 1877, suffering from eynovitie of the right knee-joint, of seven months' standing. The child had been brought up by hand, and much neglected; she was thin and delicate, had fair hair, and refined features. A splint was applied to the joint in order to keep it at rest; the temperature was normal, and there was nothing apparently wrong about her besides. On the 27th, happening to be in the ward, I observed that she was partially asleep and restless, crying out at intervals in sharp, peereing tones. The pulse was quiet and the temperature normal. I made the observation that I feared head symptoms were threatening. On the 29th the temperature was still 98.85 and the pulse 100, but the child was constantly alceping and apparently indifferent to all that went on around it. On the 30th ordered calomel gr. iss., jalapin gr. i. At six in the evening I saw the shild, with Dr. Williams, and made a note to the following effect; "Temperature 100"; pulse 130, small and thrilling; respiration 24, irregular and sighing; the pupils are of medium size, but eyes half open and unconscious since yesterday morning. Tongue covered with a creamy for; tolly concave; respiration

abdomical (probably efficien into restrictes); bowels freely moved from powder."

June 1st.—Temperature at 8 a.m. 99°; at 2 c.m. 99.6°, was much convulsed; at 8 c.m. 99.2°. During the night, alternate finshing and policy of the checks—eyes half open, but resists when oyelall is teached, and remains sleeping in a semi-concaton state —moving hands about and eyes equinting; lower cyclids shrunken, head her, pulse 170, very small; respiration quiet; bowels again open twice.

2d.—Temperature at 8 a.m. 18.8°; at 8 p.m. 98°. During the night the child was much convulsed in the limbs, and was sever at any moment conscious; roins of forehead and scalp much distended; pulse 160; respiration 20, a quarter of a minute sometimes slapsing before a respiration was taken; lips and turth dry from the mouth being half open. The tengue was covered with a thick whitish for; eyes staring; thumbs fixed in palms of hards; can swallow a little milk when put into her mouth. 4:30 p.m., pulse 136, weaker; constant twitching of right eye and arm. The motions and urine passed unconsciously for two days.

3d.—Temporature at 8 a.m. 99.4°, at 1 r.m. 100.6°; pulse 164; respiration 20. The child now bay in an unconscious state, and the right clock was much finshed; the respiration was irregular, but extremely quiet, a quarter of a minute sometimes slaped before an inspiration was taken. When turned on her side and the thermometer was introduced into the rectum she officed to resistance, and appeared not to feel it. She was quite insensible, with her eyes half open, though when the sychall was torched she appeared to feel it, and moved her head a little; motions and uring still passed under her. Made an effort to swallow when a little milk was put into her mouth. Temperature at 5 s.m. 1015; at 8 p.m. 101.6°.

The breathing now became heavy and stortorous, with macus rattling in the throat, and the chocks were livid; the lips were also dusky and the nostrils quiet. The pulse was too rapid to be counted; the temperature was taken in the axilla immediately before death at 10.30, when it reached 100.6°.

Post-marton Exercisation (becaty hours after death) by Mr. Alben Dovan.—Tibin slightly displaced backwards; no excessive synorial fluid was found, nor any adhesion but synovial fringes were varcular and by portrophied, invading the margins of the emplying of the feature, which were softened.

On removing the scalp the calvarium had a durk renous appearmee; there was perfect union of the feutapelles. The dura mater was everywhere distended and adherent along the line of the longindical sinus; there was great congestion of all the veins of every magnitude, including venous capillaries. The meningeal artery and velus accompanying it were distended. The ecovolutions were flattened, and milky pateloss of whiteness were seen over the arashnoid; texture of brain very soft. In the subarachpoid spaces there were about four ounces of fluid (clear and servers) from the locus perforatus to the medulla oblongata, the ameliouid was infiltrated with small speeks of subercle. On outting into the henispheres the gray matter was slightly congested, the penciaof the white matter exuded freely. About half an onnce of servisfleid in both lateral reatricles. The amsorial ganglia, the pourthe orurs, and medulla oblongata were all firm and free from congestion.

The right long was moderately congested, with military tellerole disseminated throughout, less at apex, where the congestion was alight, than at the base, where the long was very dark; the left long was still further congested from the presence of tuberoles. Bight cavity of heart distended. Lover and tichneys healthy. Manuforic glands all enlarged, the largest the size of a French loss, with encous tuberole in the larger ones.

Microscopical examination of the imags: Adenoid relie very feedy deposited in stream; no proliferation of epithelial linkup of pulmonary vesicles, characteristic of acute tuberculosis; death befere secondary external premnenia. Adenoid rule so aluminat is to cause collapse and occlusion of vesicles.

Chronic Easilier Meningible.—There is a needity of sease and threat meningible attacking the base of the brain (hosiles section) (b) very well described by Dr. Cross, of New York. In the ability is not a common affection; in forty seven cases of this localized affection forty-three were neuto, four only chronic, as proved by post-mortem examination. Gintrae says, "This species is distinguished by its seat at the inferior surface of the brain, by its finguished extent, and especially by the rotation of the affected

^{*} On Chronic Location Haritar Mentigitis Psychological and Medico-Logal Journal, April, 1875, p. 220.

The symptoms depend on the intensity of inflammation, as well as on its seat and extent. When a small portion of the numbranes at the loss of the brain are involved, the symptoms are not so sovere as when a larger extent of brain is implicated. Thus, the option serve of one side may be atrophied, whilet the other is normal, and the inflammatory explation or softening may extend to the third, fourth, fifth, sixth, seventh, or eighth pair of nerves, and so set up a different set of symptoms—symptoms of a local character, shifting from one side to the other. The third nerve, in the majority of cases of busilar meningitis, is puralyzed.

In thirteen cases recorded, the third nerve was partially purilyzed in nine, and in most cases on the left side; in sine cases there was strabismus, and in five of these it was external and on the left side; the pupils were diluted in eight cases, and contracted in one; there was obscureness of vision in four; ptosis in five; blindness in one case; in another loss of eight in both eyes. Headarhe was a prominent symptom, not confined to any particular locality; in twelve cases generally severe, dull, and throbbing, and ashered in gradually; once it was developed anddenly. Vertigo was present in seven cases, paralysis in eight cases. In acute cases, paralysis is the exception, exclusive of the nurseles of the

eye. In the chronic form it is most frequently marked.

Chronic basitar meningitia is very prone to change its position from one side of the head to the other. The symptoms may be well defined on the left side, as prosis, strabismus, dilatation of the pupil of the left eye, and headache may be marked on the left side. These may disappear, and the paralysis be enred, and after the inported there mouths the patient may have the same symptoms on the other side. In one case the disease was usbered in by poleptiform convulsions, and once by the less of consciousness. Anasthesia was present in six cases, sometimes confined to ets ade of the face, generally to one arm or leg; once in the left limbs, and in the right arm; hypersythesia in no instance. The above are the most important symptoms of chronic basilar ments gitis; but the following symptoms are related in the thirteen cases alluded to: comitting, twice; thirst, thrice; trismus, thrice; fever, once; supination, once; episthotonos, twice; musea, one; eyes closed, twice; coma, once; dyspnou, once; convulsive morements, once; aphasia, once. The chronic form is most common

^{*} Maladies de l'Approvid Nerveux, vols li, Paris. Quosed from Dr. Gross

between the ages of twenty-five and thirty-five; the acute most frequent between one and ten years of age.

The diagonals is exmetimes attended with perplexity, as there is no one pathognomenic symptom we can rely on. The ophthalmescope is a great and to diagnosis; and if the eves are in a normal state, and there is no disease of the orbit, we may reasonably condufe that the disease is central." The difficulties, however, are not so great as they are sometimes made to appear, for in nearly all cases I have seen of chronic moningitis, or tubercular moningiris, there are symptoms present that point to the base of the brain as involved in the irritation, and I have never seen a case after death where the post-mortem has not revealed exudative changes in the latter situation. This exudation of congulable langer may have an affinity to gather round the great nerves, at the base of the brain. Even where tumors or costs in the brain are supposed to be present, or softening or embolism or homorrhage to have hargeened, the duration of the symptoms, the localized palu, and the implication of nerves would assist the diagnosis.

Treatment.—This discuse is so uniformly fatal that if the practitioner is sure that the meningitis arises from tabercles in the membranes he cannot hope to save his patient. I have never known a case recover. We have already seen that in simple meningitis death usually takes place in a few days, and in the graver disease under consideration we have not only cerebral in-

^{*} The stilly of the ophthalmoscope in elacidating the intraerabil discuss of shibben is stone in the following passage: " L. Heingel (Jahrbach der Kindesheifbasis, rel. iii), in our time cases of interestial disease in children, south in fortywrom affections of the optic serve or roting, or of both. There were eighteen cases of benomiaitis; shirtees of researcieries with concerted papella; four of competitue of the optic seese; four of optic neutric with congested pupilla; two of consentite stripty of the casic nerve; six of strepty (genuine t) of the optic serve); and in sixten the epithaliar scope appearance was around. The cost are thus cholled secretary to the discover in thirty one cases of taberration maningities of the base of the brule: Given of neserveticitie, five of associabile with congested pupills, forof respection of the uptile nerve, two of incipions strophy, one of atrophy, and frue with around funder of the type. In two case of the same discounterful of street, and ther segment these of seminorization are of optic mention with competed pupills, line of steady of the systemetre, and from normal. In ferrious own of confeed the if renorminitie, two of neurocottoms with subsequent arrests, four of aboply, and these weard. In this case of orders cerebri-congestion of the optic were. In the renaining seven rates judama and hypercenia of the meninger, otheron of the horizon condempinal meningitic, and offmion in the cords, the finding of the age was mercal. It was observed that nearcreting in frequently appeared within a few lays, and that is all cases it affected both eyes slike " - British Matical Journal, Oclabor 1616, 1875, p. 452.

flammation to contend with; but an inflammation kept up by the irritation of tubercular deposit. When the disease is threatening, every attention should be directed to remove all sources of irritation that lead to cerebral congestion. The mental powers should not be taxed by lessons, and active remedies should be discontinued. The head should be kept cool, and the bowels gently stimulated by the mildest laxatives; the dist should be nonrishing and matimulating, and the heat of the sun avoided. Pure air, lively companions, and cheerful surroundings are important; running and active physical exertion should be discountenanced.

The occurrence of perrigo and eletinate eruptions of the face and head require careful management, especially during dentition. In the autumn of 1874 I mer with a fair and delicate child, two years of age, who had an active eczenatous eruption of the whole scalp. It had remained obstimate for menths, sensetious being day and covered with crusts, and at other times discharging freely under an oil skin mp. When the oraption oventually healed the child developed strumous symptoms, and the health began slowly to decline; the face shrank in size, and the reins in the heal were fuller; shop at night was restless and unrefreshing, and the child refused his food. After several convulsive sciences an attack of meningitis supervened, and death occurred in the course of a week. No post-morton was allowed.

These cases I now regard with caution, and prefer the continunace of a mild skin affection, even if disfiguring, to the dangers incident on suddenly healing it.

Antiphlogistic are the chief, if not the only, remedies by which we can hope to affect relief. When the earliest symptoms are threatening, as least of head, previsioness, and irritability, a grain of coloned alone, or the hyd. c. creta, with a few grains of ristlarb, will be necessary for two or three nights in succession, or the dose may only be required twice a week. A mixture of sulphate of magnesia is useful during the day, with a small quantity of the tincture of bark or nitrate of potasts, if the skin is hot and the urine sensity. The infusion of calumba and syrap of clubsers, in equal proportions, is a good stomachic and laxative. If there is any tendency to vomiting or handarhe, caloned at the outset is the best remedy, as it is retained on the stomach when other drugs are expelled; not that its good offsets are attributable to any specific action, but it thereoughly unloads the liver and small intestines, and so indirectly relieves cerebral congestion. With regard to de-

pletory measures we have so remember that the subjects are defirate and of strumous constitution, and therefore the administration of mercury and purgatives, important as they may be at the onset of the disease, will need great care and judgment as the discase advances. Whatever is done in this way must be done early. The same remarks, as in simple meningitis, are applicable to bucker; they require to be employed with the utwost caution, and are only of use in the early stages of the affection, even if they are then demanded. If employed at a later stage, when the mind is getting confused, and there are consultive movements, the loss of loost will haston the fatal issue. Cold to the head, when there is artive congestion in the carly stages, as I have previously recommended, is a remedy of great value. In the stage of edinsion, when there is restiencess and sceplesmers, iodido and bromide of potassing will be found valuable because of their power in diminishing excitability and tranquillizing the nervous system. Those two renelles given together may control scretion, and even favor absorption if it has occurred; bromide of potassium administered alone is capable of lemening reflex action, of controlling convulsive solutres, and of reducing to some extent arterial tension and vastular excitement, when the more depressing action of chloral night be considered hazardous. Morphia or an epiate in some form may be required when there is excitement and wandering, and the little patient can obtain no sleep. But great caution is becoming in administering these remedies from the cerebral actirity to which they give rise at first, and the danger of subsequestly depressing the circulation, and lessening respiratory action. Opium nets equally upon every nervo-cell, and also equally upon every acres filtre : it not only lessens cerebral receptivity, but it also deaders; nerve conductivity," A sidative will semetimes be home well after the action of calend and purgatives, if there he scarcely any heat of the head, and the pulse be quick and feeble.

I house hydrocypholos, or dropsy of the brain, consists in a colbetion of acrous fluid within the head. It may commence in atero and seriously impose the progress of labor, when it is termed congosital hydrocephalus, or the head may not begin to colarge till after birth. In most cases the fluid is effused into the ventricles finternal hydrocephalus), but it may collect between the dura mater and the cranium, or between the dura mater and the amehsoil, or between the latter membrane and the brain—external hy-

Brit Med. Journ., vol. i, 1876, p. 16.

drocephalus." Wherever the accomulation takes place the symptoms are nearly if not quite alike in all instances. Where it is efflused between the arachnoid and the brain, the effect is to fatten the convolutions, if not to obliterate them, and to expand and increase the width of the head, which also becomes clongated, and the base of the skull depressed and hollowed out. When the accomplation takes place in the ventricles the brain becomes thin, and spread out so as to be almost obliterated; and if the fluid meets on the two sides, the homispheres are pressed number, and the distension stretches the pia mater so that it can scarrely be seen; the cerebral tissue being infiltrated by the effered fluid, becomes soft and pultureous, and otherwise altered. The lense entering into the formation of the skull become thin and friable from the diminution of bony matter, and ossification is incomplete at the anterior footswelles, and along the line of the coronal suture. The water may go on impreasing till the entures separate, and the ventricles become distended with as much as three pints of fluid, without any water exterior to the brain. Such a case is related by Dr. Underwood. The effusion is greatest in the earlier months of life, and lessens or remains stationary as the child gross sider. When it is congenital, it is due to some morled state of the membranes, or restricles of the brain, and is either observed at birth or soon after.

The fluid consists chiefly of water; traces of albumen, place plate and curbonate of line, and potash are found. It is tranparent or slightly yellowish, and the specific gravity is lower than the serum of the blood from a deficiency of solid constituents. In the well-known case of Cardinal, who was hydrocephalic from infancy, and attained the age of twenty-nine years, the composition of the fluid was found to be:

^{***}OX 200 cases of hydrocophains I have found 200 to be of the internal variety, M to be ordered of the pin mater, 10 to be cases of external Applicorphains, and 10 and of simple careful ordered. "Stainer's Disease of Children, by Lances Tail, p. 64.

[†] On the Disease of Children, by Dr. Daviss, 1846, p. 272.

I Joses and Sicroking's Pathological Amissay, by Dr. Payne, p. 248.

Crees.—The disease is frequently hereditary, and is not with in the families of drunkards, and those affected with syphilis and consumption. Children labeling under mesenteric disease are label to be attacked, and dentition is an exciting cause, as also rickets, by preventing or retarding the ossification of the skull; an attack of bronchitis or diarrhou will awaken the disease in a child prollaposed to it, and some parents profess to truce it to a troublesome saturch. Excess or deficiency of blood in the brain, impelling the cerebral circulation; hemographic into the sac of the arachnoid, morbid growths, or a slow form of inflammation, have been connected as common causes.

Symplans,-Some enlargement of the child's head before the health legins to fail is generally the first symptom to attract notice, but a strange movement and unstendiness of the even, which is set down to gastrie disorder, may be among the early inficutions. In some instances, nothing is observed till a convulson happens, and from that moment some marked signs enems. The face has an old and shrivelled look, and is very small when compared to the size of the head, the chin being pointed, and the angles of the lower jaw sharp in outline. The appearance of teeth is delayed, and children often seach their first year without any tmore of them. The eyes at an early stage have a slow rotatory movement, and the veins of the hand become distended, as though about to burst when the child cries; the skin of the neck and buly is loose and wrinkled, and the stomach is noticed to be large, whilst the extremities waste; the howels are knogular, being sometimes constinued and at other times loose; the motions are light or dark and offensive, or clay-colored and sticky, or they are greenish and contain undigested matterlike curdled milk. There is apparent disconfeet about the head, and the child is constantly raising his fingers to his eyes, or passing his hand across his forehead; he is frequently sick during the day, and retains nothing on his stensack. In some cases the appetite is ravanous, and the child is only quiet when he is eating; in other cases the appetite will depart for days together. Having reached this stage there are striking changes to be observed in the size and shape of the had. It may have been noticed to be larger at birth, or to have commenced to grow disproportionately within a fortnight; but notwithstanding this, the child may be plump and healthy-

^{*} West, on Discusses of Children, fearth edition, yo. 117.

looking, able to suck, and apparently well sourished. Soon, hereever, and frequently between the uinth and twelfth month (when the mother leaves off suckling, or the dist is changed) autrition is interfered with, and the child begins to lose flesh and growweakly. If he is older, and has been able to walk, he totters, and his logs cannot support him; he is wearied after exertion, and falls off to sleep in the daytime, and is mable to support his head; he is uneasy and restless at night, and the pillow has a wet circle where the bend has laid. As the cranial hones yield to the increasing fluid, the veins of the scalp become distensied, the temples sink in, and the forehead is arched, whilst the auterior fontanolie is open, and the frontal hors itself is only completely unified at the lower half. In one case under my care two large veins randown the groom, and when the child cried they looked about to rupture. As the effusion advances, the parietal and frontal bones become more separate, and their olges are to be felt if the distansion is moderate; the eyeball is now prominent and theorem downwards and forwards, and the selerotic between it and the upper evelid is very prominent, whilst the lower evelid conceals the pupil. If the fluid increases rapidly the child may become downly and heavy, and symptoms of compression casue, followed by squinting, convulsions, irregular pupils, and comm. In the course of hydrorephalm, before the head is much enlarged, Dr. West has noticed in several instances, spasmedic attacks of difficult breath. ing and crowing inspiration like spasmodic croup."

Freshaust—This is a most unsatisfactory disease to treat, at whatever stage it comes before us; not, however, that it is always incurable, as instances of recovery are recorded, and hydrocephalic children have reached manhood. Where the cerebral functions are not seriously implicated, and ecorulations and paralysis do not arise in the course of the disease, we may hope for benefit from treatment if we see the case early, and the child's constitution is

tolerably robust.

The strengess employment of moreovial immetion for weeks, in the shape of one or two drachess of the mild unguentum hydrargyri, robbed in daily over the shaven scalp, has proved teneficial. It is a plan recommended by Professor Gölis, of Vienna, and approved of by Dr. West, 1. The head is to be kept constantly overed

^{*} Discous of Children, faith edition, 1886, p. 120.

Plid, p. 128.

and protected from the cold by means of a tightly fitting flame! cap. A quarter to half a grain of culturel is to be given twice a day, unless diarrhora comes on, when it is to be discontinued, and immedian alone trusted to. If at the end of six or eight works no benefit results, digretics and other remedies are to be used, and house or blisters applied to the back of the nick. A very instructive and apparently hopeless case is recorded by Dr. Underwood. After leading and purgation, two deathous of strong mercurial outpost were rubbed in daily for three weeks, and a powder cossisting of a grain each of squill, digitalis, and calonal was given night and morning. An improvement soon commenced and gradually continued; the child passed through destition well, and at twenty-one years of age was a fine young man. Merenry, like other exhaustive measures, sinst be used with the utmost cantion, as prostration of strength is easily induced. If there he restlessness, great heat, and turgescence about the vissels of the head, leading have, according to some authors, been repeatedly used with advantage, but I have laid no experience of the plan, never having seen a case in which I should have felt justified in employing them. The treatment found most serviceable is to meet the this symptoms that are present in each individual case; if there is diarrhou, or broughitis (not unfrequent complications), it must be subdued before any active measure are adopted, or the child may die of convulsions or synerge. Where the symptoms are though careleal, and the child is well nourished, moreovy is best tolorated; but if there is much wasting and emaciation, and the palso is foelds or irregular, it cannot be trusted to. Looking at the cases as a whole, I have found small doors of the hyd, o streta of besefit, continued every night for a week, and then left off for a short time and resumed again. If the strength is equal to it, I prefer the sixth of a grain of calomel night and morning for a four days, when the head becomes cooler, and congestion and sickness are relieved. Where mereury appears to be indicated, we may obvinte the dangers of depression by employing small doors of the solution of perchloride of morenry with the fincture of cinchom. As in some other cerebral affections it will be found a valuable combination.

The indide of potassium is another remedy on which I repose

^{*} Discount Children, by Dv. Darses, 1844, p. 174.

comblerable faith in the management of these cases; it is of undoubted value where there is irritability, and the head is doubly getting larger; it should be given in small doors, one or two grains three times a day, in a little syrup and water, and then it does not disorder the stomach, and cause sickness, as it might do in larger doses. I semetimes add a few drops of sal volatile to obviate any depression. In cases complicated with secondary syphilis and affections of the periesteum and joints, it is a valuable alterative, becoming irritation of the carebral membranes, and promoting the absorption of chronic or inflammatory effusion. If there is restlessness and handache, then a few grains of the bromide of potassium may be advantageously added to it.

Compression is a remedy suggested on the view that a certain degree of pressure is conductive to health. It can only be safely employed when the discuse is chronic and stationary, and there are no active signs of corolard disturbance. When the child is pale and languish, and fluctuation is distinct between the imperfectly ossited benes, the head may be strapped. Narrow strips of plaster are made to encircle the head from one masterid process to the other, and from the maps of the neck to the root of the ness. If symptoms of pressure at the brain or heat of head follow the application they must be loosened or removed altogether. Whilst this local treatment is being carried out, the functions are to be stimulated by dimentics, alteratives, and an consistant parge. Preparations of Iron and condiver oil are generally needed, scorer or later.

Practice.—This should be done at the coronal suture with a fine trocar and conula below the anterior fontancile, avoiding the longitudinal sinus and large veins, gradually mithdrawing the fluid and keeping up pressure on the head as it discharges, lest the pulse become weak and feeble, and the child faint. I know of one case in the practice of a medical friend in which a cure was said to have followed this method, but I have had no such experience myself, and I should be reluctant to adopt it unless all other means had failed.

It is wellnigh impossible to frame the definition of a disease so variable in its manifestations as spilepsy, the severe forms bearing but a faint resemblance to the milder varieties of this affection.

Epilepsy consists in the occurrence of fits at more or less regular intervals with entire less of sensibility and consciousness. In its serere form it is accompanied with general convulsions, and spannedic contraction of the voluntary muscles. It is frequently followed by deep sleep or come. Males are said to be more subject to the discuss than females, but Russell Reynolds considers the two sexes about equally liable. Except when occurring in imbaciles, severe cyllepsy in shildren is of very serious owen.

It is important to remember that the spasmodic action may vary from slight twitching of the arm or leg to the most severe convulsion, and that the degree of consciousness may range from more bewildermout and confusion of ideas to the most profound come.

Epilopsy is divided into two varieties. I. Epilopsy proper, or

idiopethic opilepsy (Le grand mul). 2. Slight spilepsy (Le peth mul).

Epilepsy may be centric or excentric. When centric it may depend upon irritatio areas in the brain; irritable by some inhorized tendency, or some accidental injury or mortid growth. When of excentric origin it may arise from peripheral irritation, as a topeworm in the intestines, or some abnormal condition of the viscus. "Scientifically, I should consider epilepsies on the hain of each being dependent on excessive paroxysmal discharge of some part of the cerebral cortex."

The epileptic discharge, though single, if severe may produce the same shock to the rest of the brain, as is the common result of a series of rapidly repeated fits; the "states epileptics" or condition of complete prostration following a series of repeated fits is strictly analogous to the condition of exhaustion produced in the electric sel (Gymnotus) after repeated discharges, or the condition of fish after the explusion of guspowder or dynamite in a pool.

Death from the first epileptic discharge is exceedingly rare.

Whose it does so take place, the brain and membranes are found enermously congested if the seizures are prolonged. The heart is arrested and brought to a standstill, either from exhaustion due to the violence of the fit, from paralysis of the medulla, or from the circulation of carbonized blood producing asphyxia.

The symptom of the so-called true or bliogathic form of epilepsy are endden loss of consciousness, "a paroxysmal loss of consciousness" (Hughlings Jackson), the patient frequently screams out in a lossi voice, as if alarmed or terrified, and usually falls with his face forward to the ground in an instant if standing up or walking across a street or room. He may, however, fall backwards or to one side. Proximity to a fire or water at any moment may put his life in jeopardy. He is likewise at the risk of injuring himself by coming in contact with some hard hody or sharp surface. Cats and braises are common amongh under these circumstances. Terror and a sense of fear frequently precede an attack. In the seizure the child throws his arms about and kicks violently, the muscins being tense and powerfully contracted; the conventions may be general, but as a rule, one side of the body is more affected than

³ Lectures on the Diagnosis of Equipper, by Haghlings Jackson, M.D., The Leavil, 1873, p. 45.

the other; the eyes are wild and fixed, or so hidden by the upper life that the scierotic is only exposed. The pupils are morally dilated and insensible to light, but at an early stage they are often contracted, and of variable size during the continuance of the paroxysms. The pulse may be so variable that it is scarcely perceptible, or it is not altered from houlth, whilst the hourt is felt to be violently beating and the carotide are equally active. The expression is greatly distorted; the face is palled at first, from tonic contraction of the vascouctor nerves, but it soon become fired, and the superficial volus, including those of the head, are turgid, and the mancular conts of the bloody-seels are involved in spo-Sometimes against mixed with blood issues from the namely. Small extravasations of blood on the surface of the face and forehold are semionally seen resembling perceive. The tight dosure of the jan a often causes the patient to bits the tougue or the under lip. The contraction of the flexor tensions is always great, the Supers being elenebed in the paims of the hands, the fost arched, and the toes bent.

The insensibility may be so profound that the patient cannot be roused by any means at our communal, and even reflex action cannot be excited in severe cases by tickling the feet, or irritating the conjunctiva. When the parexyem has subsided, the skin is bothed in perspiration, consciousness returns, and the patient may seem note the worse for the seizure; but is usuay cases there follow perfound aleep, and on awaking the child may be torpid, and his memory and ideas confused for a day or two. He complains of frontal hundache, and the features are so congested and Monted as to be almost characteristic. " Handache and vertigo are the two forms of disturbance the most frequently complained of by epilepties " Headische is common both lafore and after the seizure. Dr. Sleveking met with it in 55 aut of 101 cases. He speaks of it as " Cephololysis spolephylomies," and says, although the pain may affect any part of the head it chiefly attacks the vertex. In the mics I have observed there have been the soul characters of comgestive herdnebe from excitement of the circulation and fulness of the cerebral vessels ! Semations the contours of the bladder

A Kyasan of Moderns, article Epitoper, by J. Re-40 Bornello M.D. vol. ii., p. 215.

[†] On Spileyer, 2851, p. 86.

I On Headington by W. H. Day, M.D., 1875.

and howel are passed involuntarily during the fit. The tenic conruisions continue for a few minutes, and then pass away, having the muscles more or less flexed and extended. Sleep may continue for some hours afterwards, the muscles being completely relaxed or trouplous. The fit usually lasts two or three minutes altogether, but it may exatinue for a quarter of an hour. "The first or totanle period is generally the shortest, lasting from a few seconds to half a minute or one minute; while that of the cloude convulsions is the longest, and lasts from three to six minutes." (Althous.) In some cases of epilepsy the patient is no scoper free from one fit than another supervenes. When this happens, the brain suffers from these repeated shocks, and in the intervals of the parexysms the child is torpid and prostrated. There may be several fits in the course of the twenty four hours, or the interval may extend over months and years. "The number of attacks in a given time ranges between very wide limits, from two to two thousand in a year; lest half the cases are found to have a rate of recurrence ranging from one attack in fourteen to one in thirty days ""

"What is called night-alarm or nightmare in children is often an incomplete epileptic attack. The children go to bed and sleep in the usual manner, but after a time scream, endeavor to get out of bed, stare at some imaginary object, break out into a profuse perspiration, full back exhausted and relaxed, and go to alcepagain. Such attacks may be repeated several times in the night, and the little patients have no recollection of them on waking in the merning." A child agod three years, suffering from rickets and errebral exhaustion, was under my care in November, 1879, and the narse found him night after night in the condition described, but he never had a genuine convulsion or spileptic paroxysm. Broudbe of potassium and hendame relieved the symptoms.

In some cases the urine contains an abandance of phosphates, alternating with an equal quantity of lithates. "Frequently there is an excess of phosphates; exalates are often seen; and I have repeatedly found the urine of epileptics exhibit persistently so large a quantity of urea, that, on the addition of equal parts of

^{*} Barrill Haywolds, up. etc., p. 315.

[†] Lectures in Discount of the Nurvini System, by Julius Althous, M.D., Midfell Execution, Feb. 7th, 1878, p. 112.

ritric neid, the whole of the liquid was almost solidified by conversion into area."*

An epileptic seizure does not always commence in the same way. Before the attack, in some instances, there is pain in the stomach, nausen, or vomiting, headache, and restless sleep. In other cases there are pain in the precordial region, and pulpitation of the heart, bright colors appear before the eyes, there are union in the ears, and nervous apprehension. The patient often looks wild or tacant, and the mouth and lips are in constant movement. If the torges is protrated there may be seen on its surface a formy sairen, which is not infrequent among adults who suffer from prevent disorders. "Children particularly show the alarm they experience by running to and clinging to their nurses and mathers." A psynline facting of cold, or tingling, or numbers, or reportsh smeation, creeping from the lower extremities, is felt along the spine to the back of the head (termed the "aura"), when the patient becomes insensible, and falls down in the fit.

The ones collective is a curious physiological phenomenon which indicates the approach of the purexysm. It is a premonitory erroptom, occurring in about one-half the cases, and is subject to much variation in its character. Sometimes it is motor in its origin-convulsions solzing on a certain set of muscles, as those of one urm, or leg, or foot, or finger. Many years ago, a young lady came under my notice, where the parexysm was proceded by inresunt tremor of the right leg. She called out, " I am going to have ague?" and then the fit followed. There was probably vasomotor il sturbance, and a sense of chilliness at the same time extending spwards from the limb to the brain. Some astro seem to sflect the nerses of special sense, as when offensive, strong, or Esigrerable odors excite a paroxysm, or flashes of light are seen before the eyes. Commonally the aura may be viscoral, as when it affects the stomnels, heart, or intestines. Any sudden shock, as raling aload, tying a ligature round the limb, or giving a stimulist, may arrest a seizure even when the aura is present.

Dr. Hamifield Jones mentions the case of an epileptic boy, 18 years of age, in which the fits begon with a sinking sensation of the stouach, then giddiness and falling down, but there was no anonodousness. After a "fright" he got well marked choren, but he was free from spidepsy. The author remarks that "the

^{*} Un Epilepsy, in E. H. Sirveting, M.D. 1861, p. 117.

transmutation of the unlady into chosen is a point of much interest, marking the affinity which subsists between the several neuroses." The nurs or reflex action in such a case would probably travel to the medulin ablongata by means of the sympathetic and preumogastric nerves. There is a similar relation to asthma.

Not unfrequently the disease is preceded by a voracious appetite or constitution, in others, on the contrary, by a total dislike of food. In most cases there is no notice of the fit before it cours, Agitation and excitement are instantly followed by awimming in the head, the room appears to go round, and the patient falls down.

An epileptic fit may be preceded or followed by spitefalness, anger, and violence. The shild is shy, fretful, suspicious, wilful, disobedient, or merose. Dr. Sleveking has observed "thiering proposities and other mischievens tendencies, such as setting fire to dwellings." Dr. Althous has recorded a case, in a low of 7, who had regular uttacks of destructiveness, tearing sheets, blankers, elselies, and everything within his reach. "After a particularly bod outbreak he was put in a strait waisternt, and managed to tear it to pinces with his teeth." In another case under his cary, a girl of 9 was a "fearful liar," stole money, and was during and defiant. A girl, " years of age, was brought to me by her mother, in 1872, who was in the habit of suddenly rushing at her sisters and brothers before the peroxysm, and biting them, after the fashion of a ferorious dog which had been teased and irritated. The arms of one sister showed indentations caused by the patient's teeth.

The part sud is a less severe and frequent form of epilepsy, consisting in gibbliness and confusion of ideas, or sudden and transient loss of consciounness, accompanied with symptoms of faintness or of syno-que. There is slight convalsive moreovest of the facial muscles, eyes, and knods, or may be not even this, followed, by stuper and sleep. The patient may stagger, and even fall down, or may exhibit such a wild and vacant look that a by-tander thinks a fit is about to happen. "To prevent a possible misunderstanding, let me remark that the terms "slight" and "severe" refer to quantity of manifestation, not to gravity of the case, the slight

^{*} On Familiani Nervou Disciona 1870, p. 293.

Molicul From and Citerian, July 18th, 1973, p. 43.

sciences are the worst for mind." When the convulsions are severe, the insensibility complete, and there is biting of the tongue and framing of the mouth, the diagnosis of epilepsy is easy enough, but epidepale vertigo with partial suspension of reason is age to perilex us in diagnosis. In some of these attacks the speem is secretly shvious. The respiration may be momentarily seconded, and the face at first pullid becomes livid, whilst the urine is frequantly discharged during the seizure. "A boy, 10 years of age, had been subject to fits for two years. At the first they were so slight that his mother said they thought he was in a tdeep study ? he used to sit 'as if he were thinking.' The attack was only of a few seconds' duration, and no alteration of complexion was perioad. Later on in his fits he would turn up his eyes-slight spans of very small muscles. Later still, there was, besides this, occasional shaking of the body (mitated before me by fromor). I saw one. Whilst sitting the boy blinked his eyes; he did not after in rolor; he then drew in a deep breath, and rapidly all was over-The purexysm was so sudden and short that I could not make my special investigations. Attacks of epilepsy may be so slight that strangers sitting opposits a patient at dinner may observe arching, although there is absolute, though transient loss of consciencess. + These slight seizures may come and go, and then be replaced by the severe forms of epilopsy. "Le petit mal" may occur with or without spasm. In the former there is a sudden or temporary loss of consciousness lasting for a few seconds, and then passing off without the patient knowing that anything has happened. In the latter there may be slight spusm of the facial or brangeal muscles, or the spasm may be brief and slightly isvolve the whole voluntary muscles of the body. "The most common combination and degree of symptoms may be thus described,-a feeling of giddiness, faintness, or discomfort; slight twisting of the neck, with anxious lachrymose expression of the face dilatation of the supils and pallor, accompanied, or quickly tillowed for entire loss of conscionsness, which lasts for two or three seconds; the patient becoming himself again after making

* Highlings Jackson, ep. cit., p. 42.

I Br. Hughlings Jackson, On the Diagnosis of Epilopey, The Lamest, 1970, vol. i., p. 63.

a few righing sounds, but feeling faint and bewildered, and often persoiring freely."*

The crosses that predispose to opilepsy are various. The discuse can often be traced to hereditary influence, the purents or some member of the family having suffered from it; or there is a history of insunity or some other neurosal affection-such as an originally weak or susceptible condition of the nervous tissue, liable tomorbid action. Long-continued debility and gastric irritation. or any source of exhaustion, as chronic diarrhou, albuminaria, musturbation, etc., are among the factors which lead to the epileptic paroxysm. Hereditary syphilis is another cause. Rickets would also appear to be a cause, just as it is of eclampsin. "At least three fourths of the cases of epilepsy, dating from influer, are believed to be the consequence of rickety convulsions." The relation between heart disease and epilepsy is also very close, as out of sixty-six cases observed by Dr Gowers, in which the two diseases were conjoined, in twenty-five there was mitral or acetic disease. He thinks the cardiac disturbance is due to one of three causes. 1. Irregular action. 2. Simple dilatation. & Valvular disease. These several conditions would appear to be either the consequence of the spileptic paroxysm, which puts a violent strain on the heart, or the fits arise from the cardia: affection.

In a boy, 9 years of age, who came under my care in 1815, there were the symptoms of pulmonary consumption. I have observed the connection before, though not often enough to justify me in saying that it is more than casual. Phthisis is far more common than epilepsy, and o sen the two diseases occur together there is probably a state of the nervous system which reality invites an epileptic parecepton. The patient had been losing fiesh and strength, was much wasted, and coughed chostly at nights. Whilst under treatment a fit occurred for the first time, lasting an hour and a half. This was followed by homophysis to smally a pint, with the physical signs of tubercular disease of the lurgs. These various influences reduce the bedsily health in such a manner

A System of Medicuse, setting Epilopop by J. Remell Revands, M.D. vol. 6, p. 300.

[†] On Some of the Causes of Epilopey, by J. R. Gowen, M.D. Medical Swire!* Proceedings, vol. 1v, p. 209.

[|] Heart Disease and Epilopsy, Scir. Med. Journ., 1977, vol. 5, p. 750.

as to enfeeble the nervous system and determine an outbreak in susceptible subjects.

The serious causes are fright and terror, outbreaks of passion, musturbation, assemia, and intestinal worms. " A boy, 18 years of age, was frightened a year ago by a snake; a month after the fright he had a strong epileptic fit. He is now a confirmed spileptic; his mauner is sullen and dogged, he refuses to take his medicine, 'because he does not like it;' he has on several occasions threatened his sister's life, by brandishing a knife; he presents a physiognomy indicative of mental aberration, and will have to be removed to an asylum. There is no family history of neurosis, and the mental condition appears to have been produced by fright.". In a child aged 4, who came under my care in 1875 fir quileper, the fits commenced at the eleventh month, during dentition; another fit recurred at two years of ago, and there was an interval of two years before the next came on. The child had enlarged corrical glands, and a severe eruption of impetigo. In another case under my care in 1876, a girl, 10 years of age, had an occasional epileptic seizure, which followed searlet fever three twars previously; still there was no kidney disease.

It is also to be borne in mind that there may be a tumor, or an absects, or a spicula of bone growing from the skull and irritating the membranes.

An accidental blow may drive down a spicula of the brittle inner table of the skull, or produce a spot of localized inflammation and adhesion which may lead to repeated epileptic fits. "A boy retelved a violent blow on the head from a cricket but. He did not appear to suffer any inconveniences from the injury until ten or shown years afterwards, when he became subject to paroxysmal attacks of headachs, associated with extreme vertigo, clearly of an epileptic character. He eventually had a succession of severe attacks of epilepsy, which continued for a period of five years. He ultimately died in a violent epileptic paroxysm." Many cases of epilepsy are traceable to blows and injuries of the head.

There is a close relationship between the convulsive affections of shildren and congenital talipes. Operations for the cure of these

^{*} Phenomena accompanying Epilopsy, by Dr. Bunnerd, Scit. Med. Journ., 1877, ed. R. p. 720.

¹ On Observe Diseases of the Brain and Mind, by Forbes Worslow, M.D., 1800, p. 674.

deformities have been followed by epilepsy. Just as in some adult women, the subjects of hysteria, distortion of a limb will follow repeated paroxysms, demanding mechanical treatment till the irritation subsides. Mr. Brodhurst records the following instructive case: "February, 1852, I divided the tildal tendous and the tendo Achillis of a strong pleshoric infant, fourteen months old, for the removal of congenital varus. Both feet were nearly equally distorted. I had scarrely commenced the operation, when the child, crying violently, was seized with a tit; and I then learned that, when seven months old, the child had whooping cough, which was followed by a succession of slight fits; and that, at intervals, on coughing or crying violently, the fits recurred. The feet were after some months perfectly restored, and the supports were at length removed and discontinued. Seventeen menths after the operation the child again had a fit, when both feet were drawn into the same distorted positions as at birth. The father of this child was epileptie. "a

Mr. William Adams has pointed out that it is only in cases of rigid muscles that epilepsy occurs, the muscles being rather spasmodic and spatic than floccid, as in the truly puralytic class, where they take on fatty degeneration.† The author describes a most interesting case of a boy, 14 years of age, who fell under his care for rigid muscular contraction of both legs, and deformity of the fact. The affection commenced from infancy. "He had been for several years subject to calleptle fits, the continuance of which had, to a slight extent, weakened his mental rigor, although his bodily health remained good. At the time I may him the fits necessary regularly once a month."?

occurred regularly once a month.

Morbid Annuage.—The brain is sometimes congested, and the vessels are too full of blood, but the pathological changes may be entirely negative, there being no relation between them and the violent symptoms that have been noticed during the science. Dr. Hughlings Jackson thinks there is thrombosis or embolism of the small arteries in most cases; and he bases this opinion on the fact of having found epileptiform sciences common in those patients suffering from valuntar disease of the heart. He is of opinion that there is evidence to show that the pathology of the disease is more "arterial" than "nervous," There are many cases in which

^{*} On Christian, 1851, p. 57.

¹ Bid, p. 350.

I that, 1970, p. 61. I the cit. p. 113.

more or less hemiplogia is induced by optlepay. "In these cases I do not doubt that there is embolism or extravasation. The frequent presence of external extravasation justifies the view that a similar condition occurs in the brain. The hemiplogia is sometimes very evanuacent." (Sieveking).

Schroeder van der Kolk thinks that the less of consciousness in epilepsy is due to the excited action of the garglionic cells in the medulla oblougata, which extends its influence to the vanomotor nerves of the brain; and he believes, moreover, with Kusamaul, that in an epileptic fit the whole brain participates more or less in the change; the commencement of the fit or of the discharge is to be referred to the exalted sensibility of the medulla oblougata.

Dispress's—Vrue epilopsy in its severe form, as it ordinarily occurs in childhood, is not difficult of diagnosis; the complete insensibility, the beiof duration of the fit, the general convulcious, and the absence of stertorous breathing and paralysis render it impossible to confound it with hysteria or apoplexy. The milder cases, in which there is confusion of the mind, without complete loss of consciousness, where there is reverie or forgetfulness, and paraliar sensations are complained of, the diagnosis is not so easy to establish.

Between le petit mai and epileptiform seizures the diagnosis is often impossible.

Edampsia is the most likely disease to be mistaken for spilepsy, the convulsive paroxysms being in both instances much alike There are, however, a few distinctive features which may be considered diagnostic. Convulsions are most common in infancy. They occur in connection with dentition and are repeated frequently; they are sometimes observable at the beginning of acute fibrile disorders, and particularly scarlet fever, which does not apply to epilepsy. The latter affection is often very sudden, the child at the time of the seizure being in apparently good health, whilst convulsions are often preceded by some previous illness. In convulsions the movements are more confined to the cross and field muscles than to the limbs. The frequency of the convulsive attacks disturbs the nervous centres, interferes with the respiration, and terminates fatally in asphyxia. Children solden die in an anticptic attack.

On the Spiral Cord and Medulla Oblongata, New Syd. Soc., 1859, p. 230.

Epileptiform asizums resemble the true form of epilepsy in some respects, and differ from it in others. The distinctive features, as pointed out so clearly by Dr. Hughlings Jackson, are chiefly in respect to consciousness and convulsion. In true epilepsy consciousness is lost the first thing, or very soon after the commencement of the seizure, and the convulsions are also general from the beginning. Epileptiform scinures usually begin with spann of our hand or foot (or side of the thorax, as I have observed), consciousness is lost later on, or not at all if the seizure is slight; the convulsions are local or one sided before they become general. When consciousness is not entirely abelished the symptoms are said to be frequently induced by some organic disease of the brain, as a cyst or tumor, which is not the case with true epilepsy.* A case is related by Tromsseau, where a little boy who died from spileptiform sciences, had tubercles in the brain.*

A very excitable and passionate girl, nine years of age, was almitted into the Samaritan Hospital under my care, with spileptiform seizures, December 30th, 1878. The fits resembled the petit mal where the seizures are slight. She never fell down, although she would stagger as if about to fall. Before the fit happened she was drower, strange and absent in her manner; she could not speak distinctly for some hours before the attack, and there was a difficulty in engaging her in conversation. To prevent the postbility of falling she was laid on a bed, when she soon became gradually convulsed, the right arm first, then the right leg, and then the other leg in precisely the same order. If the exchalls were touched there was no rollex excitement induced; there was no biting of the tengue, and no foaming of the mouth. The face underwent so change in color, and the pulse averaged eighty per minute. The head shook tremulously from side to side, and the eyes were closed; the fremor would sensitive continue for a quarter of an hour, then it would subside, and the child fall aslesp for some hours before a return to consciousness. The arms and upper portion of the trunk of the body were chiefly affected. The patient would have as many as three attacks in one day, then not another seizure for a work; and then an interval of seven weeks elapsed. Every fit was of the same character, but stronger such time. It was not influenced by diet, or any cause that could be

† Clinical Medicine, 1967, vol. i. p. 62.

¹ Lectures on the Diagnosis of Epilepsy, The Lauret, 1879, vol. i. p. 41-

ascertained. Bromide of potassium in gradually increasing doses, phosphorus, cod-liver oil, etc., gave no relief. Thirty minims of the thicture of hendane, gradually increased to sixty, in helf an cause of camphor-water three times a day, completely arrested the fits during the time she took the remedy. A return of the fits rame on when it was omitted, and again departed on renumbing it.

The following is a case of interest in which the "nura" was cardine. The seigures were of a doubtful nature at first, and I was inclined to regard them as due to explan protocis, but they terminuted in true spidency." E. B., st. 6, was admitted under my care into the Samuritan Hospital on December 6th, 1876, suffering from what her mother called "spann of the heart when she awoke in the morning," She was a pervons and timid shild, and easily moved to tears. In infancy she suffered from convulsions, and ever since then had been periodically subject to these seizures. From the age of two years the attacks had been more confirmed and regular, coming on about once a mouth. Six works previous to ber admission she was found insensible in the street by a police. man, and the so continued for three hours. The attacks began with pain over the cardine region, and a tremulous and throbbing setion of the heart, followed by pullor and faintness; the eros were wild and staring, and if no one was near to support for she would fall. Partial consciousness was preserved. The heart's sounds were normal, and the rhythm regular. Pulse 100; respiration 24; temperature normal. The urine was of high specific gravity (1934), clear, acid, non-albuminous, but containing much BFES.

After being under observation for three weeks, the report states that every other morning she had an attack on waking about 7 a.m., which lasted from three to five minutes. There was tremor of the facial masseles, which were partially convulsed. She was put on milk diet, and ordered a mixture containing plusphoric acid and strychnia. No fit occurred for a month, and then in my presence she suddenly screamed out, put one hand over her heart, and the other against the right wall of the chest, both being firmly dearbed. She did not fall. Her eyes were fixed and staring, and the understood nothing that was addressed to her. Her face was slightly reddened, and the lips were compressed, as if in pain. The heart's action was rather tunnituous and thumping, and the

A good many cases of angine pertons are certainly a form only of partial spinleger, "Trouscour's Clin. Med., vol. 1, 1862, p. 65.

pulse was weak and intermitted every fourth beat. The nurse, who had seen her in several attacks, had always felt the heart thump and heat against the thorax at the time of the seizure. A week later, without any previous intimation, she had another and more severe seizure. It began with general convulsive movements of the upper and lower limbs, working of the facial muscles and cyclids, forming at the mouth, but no biting of the tongue; she touch and kicked about incommity for nearly two hours, and than she fell into sound sleep for nine hours. On awaking she was partially conscious, and seemed to recognize the nurse. Every day following, for the next week, there was a fit of a similar character. Tinoture of digitalis in five-minim doses was now ordered three times a day, and then the fits entirely ceased for the next mouth. She left the hospital on March 4th, with directions to continue the remedy which had apparently kept the fits in abeyance.

Projection.—This is favorable when epilepsy arises from any cause which admits of removal, as worms in the intestinal canal, destition, etc.; but when it imppers in children over twelve years of age, and the constitution is syphilitie or serofolous, or there is a family history of nervous disease, then the complaint may be incurable. The aspect of epilepsy, however, it must be admitted, has been profoundly modified by the introduction of the broudles into our pharmacoutical armamentaria, and cases now yield to their peculiar action, over which other drugs have no controlling or constitue influence whatever. If we have approached towards a correct knowledge of the pathology and causes of epilepsy, and our treatment is far more successful than formerly, it still restaus an income and empirical basis. There is no remedy even at the present time that can be positively termed a specific, or that can lay claim to cure the affection.

Treatment.—In the management of spilepsy the treatment divides itself into two stages. I. During the fit. 2. In the interval.

During the fit it is advisable to put the child on a bed, if
there be one at hand; to loosen all articles of clothing, especially
about the neek, and to insert a piece of wood, or india rubber, or
even a fold or two of linen rag between the teach to prevent biting
of the tongue. Cold may be applied to the head, and a simpless
to the maps of the neck. When the seizure has terminated the

child is usually disposed to sleep, which may be permitted, and when it wakes up, light nourishment may be allowed.

2. In the interval of the fit the rim should be to remove all sources of irritation, as that caused by dentition, worms in the intestinal causal, constipation, congestion of the brain, general plethors, mental emotion, as fits of anger and passion. If there he evidence of plethors and follows of the cerebral vessels, a consistence on diet, steeping on a hard bed, and purgative medicines will be demanded, especially at an early stage. They should be strong enough to be effectual without diminishing vital power; rhuberls and seams, tartrate of sola, taraxacam, or easter oil. In some cases a little Hunyadi Janos or Friedrichshall water may be advantageously given in sweetened milk.

Admitting that it is of the utwest importance to diminish or remove the merisid sensibility and congestion of the medulla oblengata, all agents that excite this must be rigidly excluded, and sources of irritation removed in whatever part of the body

they may be discovered.

Except for very special reasons moretary is not to be administered in spilepsy. Where there is a suspiciou of worms, or the liver is sluggish, and the chief secretory organs are at fault, a mitenal purgo, by acting as a derivative and washing away foul matters, will scove serviceable.

Constenireitation at the back of the neck may be necessary in some exceptional cases; but I have never done more in this way than to apply a stimulating liminent to the back of the teck, which is sometimes serviceable, as the compound campber liniment and cantharistis, or the compound liminent of mustard, or

the liniment of turpentine and acotto acid.

A highly nitrogenized diet, by increasing the exploding tendency of the irritable areas, is very hactful, and it cannot be too much insisted on to watch children most carefully in this respect. The imposition on the digestive organs of more work than they may comfortably discharge, or the accumulation of indigestible matters in the intestinal tract, impairs the quality of the blood and predisposes to the epiteptic paroxysm. Dr. Merson has made some interesting investigations on the effects of diet in epidepsy. He put twelve patients, so suffering, on a nitrogenous diet, and twelve on a farinaceous diet, for four weeks. At the end of this time is reversed the plan, those taking farinaceous food exchanging it for nitrogenous, and vice werse. At the end of another four weeks the patients resumed their ordinary dietary. No decided advantages resulted from following either diet, though there was a slight advantage in favor of the faringcous regimen. The nitrogenous plan seemed to produce more dulness, stapidity, dreaminess, and listlessness. The mental condition improved under the farinaceous diet, the satients being lively and intelligent, again becoming dull and stupid when the diet was nitrogenous, whilst the number of fits increased. A higher rise of temperature was also observed under the latter diet. The urine contained more town and salts, and was of higher specific gravity maler the nitrogenous diet than under the farisaccous. The number of fee was somewhat less under the latter. On the whole, the writer considers there are fair grounds for believing that a farinarsons diet is likely to be less hurtful than a nitrogenous one." I think this view of the question will be generally conceded, and that we are right in suforcing a plain, simple, and postitions died in our legay. Milk and cocou should be taken in preference to ten and coffee, and wine and stimulants strictly forleaden.

The hygicale treatment of epilepsy in early life claims our first attention. We can scarcely commit a graver mistake than to averical the lesson it teaches us, that all drugs hitherto selected to cure the malady occupy a subordinate rank to those rules and habits of life which must be abserved in the maintenance of health. I strongly entertain the conviction that whatever conduces to the general health, and keeps the various functions of the body in proper tracking order, does during the period of growth exert such a beneficial influence on the nervous system, as to arrest or cure that peculiar condition of it which invites the epileptic discharge.

When the discuse is threatening, or it has developed itself, our first duty is to inquire into the habits and life of the shild; to remove it if possible from a had atmosphere to a healthy one, where light takes the place of darkness; to see that the sir is pure and invigorating; the sleeping apartment lefty and commdions; and to surround it with all those influences which elevate its mental and moral tone. The children of the poor shut up in the ill-ventilated apartments of Loudon have an indifferent chance of resovery, and we often witness temporary alleviation in those

On the Influence of Decl in Epilopsy, The West Hiding Asylem Leastin Departs, 1870, p. 23.

EPHLEPSY. 603

cases which are sent into the country. Impure air retards the physical strength and prevents the shild, if old anough, from getting that amount of exercise which diverts the mind and pleasurably engages it; whilst the appetite improves and digestion is strengthened. A seaside residence and high mountain air have proved of incalculable benefit.

Above all, overexcitement of the intellect, in any child who comes of spileptic parents, or who has once had a fit, should be carefully guarded against. The effect to accomplish the routine life of school is a sufficient stimulus in itself to the corebral circulation, and if there is anxlety added to it, or too o uch pressure is put upon the child's intellect, the nervous power becomes exhausted, and an spileptic parexysm is the consequence. Mothers who have the bringing up of excitable or epileptic children, should in this age of pressure and progress encourage montal rest. During the early years of life, when physical growth is most active, and the brain is undergoing expansion and rapid changes, we cannot too strongly insist on preserving the strength of the intellectual powers, that they be not overtaxed in any way.

Bromide of potassium is the great remode in the treatment of

epilepsy, and it is about the only drug on which we can rely for the mitigation of the symptoms, if not for the cure of the disease, It lessens the peculiar excitability of the nervous centres, and probably diminishes the amount of blood circulating in the brain, which may obviate the tendency to congestion, and so ward off the parexysms when this condition is a factor in the complaint. As a sedative it controls the spasmodic character of the disorder, and, by promoting sleep, gives the beain rest. It is especially indicated if the collepsy is traccable to masturbation, or to excitement of the sexual organs. Its action varies with different persons. In some it not only lengthens the intervals of the sciences and renders them milder, but it cures the disease. The drug ought to be continued for months, or even for a year, after the epilopsy has censed, the doses and the frequency of their repetition being varied from time to time according to circumstances. When emitted in some cases, the attacks return with greater obstinacy than characterized the original seizures. In a few cases this remedy

and youths than in those who have reached adult ago.""

fails altogether. * Bromides appear less useful in growing girls

^{*} Ressell Reynolds up at p. 222.

The dose may be, to commonce with, small, and increased gradually till the fits yield, or the interval is brogthened. A cidld at five years of age may begin with five grains three times a day, increasing the dose gradually to fifteen grains in the same space of time. It is important to be aware that large doses of this drug can be borne by children without had results. "Twenty and thirty grains have been no uncommon dose to reach in patients of from eight to ten, suffering from epileptic sciences, and in them I have never observed any symptoms of bromism." It may be given in plain orater with a little syrup, or in some bitter infusion. When the stixures take place during the night, a full dose of the bromide should be given just before bedtime.

A boy six years of age, who was epileptic from birth, was relieved by the injection of fifteen grains of hydrats of chloral by the rectum, after the inhalation of chloroform and nitrate of anyl had failed. The fits occurred once a formight, and both in this case and in other cases related, the drug was sometimes given by the mouth and sometimes by the rectum. The fits were thus controlled in number and severity, the pulse became softer, the

respiration free, and alcep was induced.

Iron may senetimes be combined with bromide of potassium if there is great anomia, that though it may seem to be indicated, it does not agree well with epileptics. It may improve the general health, but it aggravates the epilepsy (Hughlings Jackson and Brown-Siquard). Iron given alone is of very questionable value, even when there is great anomia. It must be combined with antispasmodies. Still, I think it should mover be overlocked that very deteriorated blood cannot maintain the functions of the nervous system in a healthy state, and for this reason alone a mild

and soluble preparation of iron may be of service in some cases. The stronger preparations are too atimulating.

The rapid loss of blood may excite the epileptic state, just as animals die of convolutes who are bled to death. Ligature of the carotida in rabbits, as performed by Sir A. Cooper, produced sensulations, so that it seems necessary to maintain the cerebral directation as near as possible at a normal standard. Anomia and congestion of the brain are both excitants of the epileptic puroxyan, but blood may be very deficient in quantity and poor in quality without producing epilepsy; some other factor being resided to invite it.

Where there is a syphilitic taint, mercury or hollide of pocassium will be necessary.

When there is dyspepsia or intestinal disturbance, and the urine contains exalates, pule lithates, or phosphates, altromariatic arid should be given alone, or in combination with some bitter inlinion.

Phosphorus is a good remedy where nervous exhaustion is well marked.

Ergot is useful in ten to thirty minim doses of the liquid extract, given three times a day. It lessons the hyperamia of the cerebral bloodyessels, and causes them to contract.

Ammonio-sulphate of copper is another remedy sometimes speken of, but I have had no experience of it. Dr. Russell Repnolls speaks favorably of oxide of zinc. Bremide of zinc has been given successfully in spilepsy by M. Charcot, either in the form of pill or syrap.*

In regard to prophylactic measures, an epileptic science may senetimes be arrested by the application of pressure, as by a landage between the "aura" and the brain, or by oncircling the threat with a fold of linen ray dipped into but water. This relaxes the cervical vessels, and also favors the removal of spassa from the vessels of the brain.

A slight etimulant given to a child just before the seixure approaches may possibly ward it off, as is the case with some adults.

I have known epileptiform seizures yield to thirty manims of facture of hyoseyamus in camphor-water three times a day, after

^{*} Rrit. Med. Journ., vol. il, 1877, p. 732.

bromide of potassium had failed. Digitalis with bromide of potassium is also most useful."

When epilepsy is associated with cardiar disturbance, neuronal or organic, digitalis may be given with advantage, provided there is no hypertrophy or nortic regurgitation. We should, in fact, observe the same rules in prescribing it as in those cases of heart disease uncomplicated with epilepsy.

CHAPTER XLIV.

The brain is said to undergo such rapid development during the first few years of life, that by the completion of the second year, when the first dentition is ever, its size is doubled; and by the seventh year it has rearly attained its maximum bulk, though its growth, according to Solly, is not completed till the twentieth year. An organ growing so rapidly, and receiving one-fifth of the whole mass of blood circulating through the body when every other organ is in process of active development, must be liable to resent excitement of any kind, and to take on morbid action. The

hence of the cranium are thin in early life, the brain-substance is clastic, and the exceloral vessels do not derive from it the same degree of support as do those of the adult, and therefore increased arterial action, as from cardiac excitement, violent coughing, or the atlanic action consequent on inflammatory fevers, subjects its twocle to falness. The development of the brain is so great, that whilst on an average in man its entire weight constitutes 1 in 36 to the rest of the body, in the average of mammalia it is only 1 to 186.* When it is considered that the arterial anastomoses are so free, it is evident that any obstruction to the supply of bloosi through the chief vessels of the brain or their branches, may exert such an influence on the nervous matter as to suspend or decange the activity of its functions.

In consequence then of this highly developed state of the nervous system, convulsions or orlampsia are amongst the most frequent and dangerous diseases which attack the nervous system in infant life. The mortality resulting from them ranks before that of the great majority of other diseases, including atrophy, the specific cruptive fevers, palmonary disorders, and affections of the largue and trackes. Up to the age of five years the mortality is enormous; but after the age of nine it is somewhealthy diminished. Males are more subject to the disease than females.

Convulsions consist in spasmodic action and relaxation (independent of the will) of the voluntary muscles, accompanied by unconsciousness. In many respects they resemble epilepsy, from which indeed they cannot invariably be distinguished. "Symptomatic or idiopathic opilepsy is only recurring columpsia, and eclampsia is merely accidental or transitory epilepsy" (Trousseau). Convulsions constitute in reality a wide term, since they occur in various conditions when the lesions are entirely different; as, for instance, in epilepsy, tetanus, chorca, and tubercle of the brain. They may happen to delicate lufants when the supply of blood to the brain is deficient.

Symptoms.—The attack occurs either suddenly, or is precided by symptoms showing undue excitability of the nervous system. The infant is feverish for a day or so before the seizure, the head is bot, the appoints is gone, and there is thirst. It is restless and starts in its sleep, or wakes up frightened; the eyes are heavy and have a peculiar rolling motion; the respiration is irregular;

^{*} Carpentar's Human Physiology, 8th edit., p. 737.

the child is in its usual health when it is suddenly seized; in others the attack comes on during some craptice disease, or during destition. On the approach of the attack the obiid atters a scream and looks vacant; the ball of the eye is troubless, and the cycleil is turned apwards, inwards, or downwards, so as is some cases to hide the iris entirely. The pupils may be contracted or dilated, or one may be contracted and the other dilated; but there is no uniformity with respect to this symptom. The facial muscles are also involved and hideous; there is frothing at the month and closure of the jaws; whilst the head is thrown backwards or to one side, the cervical and down muscles are rigid, and the lower extremities are agitated and the feet flexed inwards.

Causes.—These may be predisposing and exciting. Among the former, is a servous susceptibility inherited from the parents, This may not, however, have actually manifested itself in the form of convulsions, but there is, perhaps, a neurosal dinthesis on one or both sides, and on inquiry it will usually be found that in other members of the family there is a history of convulsions or chores in shildhood, and of neuralgia, asthma, invanity, or other disturbance of the nervous system in adult life. The children of mothers who have had convulsious themselves in infancy are stated by Tropposent to be liable to a similar affection. He quotes a remarkable case by Dr. Daclos, of Tours. "The case is that of a woman, 34 years of age, the sister of ten children, six of whom died of convalsions, and who berself had had frequent attacks of columnia up to the age of seven; those had left bekind slight deviation of the mouth and ptoxis of the left upper cyclid. This woman had ten children, who all had convulsions; six had died, five in the first two years, and one when those years old. Her youngest, whom she brought to meat the Neeker Hospital, was a little girl, six months old; three months previously she had had a first attock, which had lasted about ten minutes, and which her mother perihed to ber having given the breast to the child immediately after a fit of passion, as the convulsions occurred on the ensuing day. Death took place three mouths afterwards from serebre meningitis." Troussess also mentions the case of a child who

^{*} Transme's Clin. Mol., 1887, vol. i, p. 843.

had eclamps a from the nurse going into a fit of passion a moment before giving him the breast."

Destition has generally been believed to be the chief cause of infantile convulsions, but resent researches do not corroborate this notion. It is more in consumnee with facts to say, that the excitability of the nervous centres is excessive during the first year of life, and that slight causes, which leave hardly any effects in adults, are, in the period of the first dentition and weaning, liable to give rise to convulsive sciences.

Convulsions are frequently to be found in children who are rickety, and in whom dentition is delayed.† Here convulsions have a reflex origin. They may occur in connection with chronic hydrocephalus and strums, where the head is large and the fontanelles are open. They are not infrequently associated with laryngiamus. A rickety child, eighteen months old, came under my care in 1876; she had only three teeth; as many as six fits took place in the twenty-four hours, each fit lasting about a minute. The face was drawn to the right side and much distorted, the pupils were dilated. After each fit the child became conscious, but fell asleep afterwards. Sleep and come are, however, more common after epilepsy.

When severe cruptions of the scalp in children are dried up too quickly, convulsions sometimes follow. I have seen a few cases. A child, ten months old, came under my care in 1875, with ecsema of the entire head, the whole scalp being covered with crusts, from beneath which an irritating discharge escaped. When the bealing process was nearly completed, and the discharge had coased, the child had a succession of convulsions, which termitated fatally in three days.

Convulsions may be met with in infants at the breast, who suffer from frequent vomiting and diarrhon. The fits subside when the functions of digestion are set in proper order. Convulsions may also be observed in children who are thriving and doing well, whose howels are regular, and whose motions are of proper consisture. Whatever tends to weaken the system, such as improper and insufficient food, or profuse diarrhon, by lowering the nutritive functions, will exhaust the strength, and by depriving the nervous

^{*} Bid., p. 241.

I Of 61 echanptic children, 36 were rickety (Dr. Ger, St. Bart, Hosp. Reports, vol. in).

system of its proper support, weaken it and render it more trastable. Hence it is that diarrhou in weakly children may realily provoke a scigure. Losses of blood are equally productive of an attack. Discusses of the intestinal canal, and especially worms in the bowels, are common causes. Hot weather may so lower and exhaust the system as to bring on convolvious. Cold, by purelyzing the vasometer system, may equally provoke an attack, and exposure to night air is particularly dangerous in this respect.

Convulsions are stated by Trousseau and others to have been set up by a pin or needle, or a fragment of the inner table of the skull, sticking into the membranes of the brain, or even into other internal organs. Blisters, burns, and scalds have likewise cansel them. They may occur during the crustive fevers and acute pulmonary affections. In these cases the febrile disturbance indices hyperemia of the brain and membranes, the vessels carrying too much blood to the head, and that at an elevated temperature, as may be witnessed in some cases of meningitis. When convulsions occur in association with whooping-cough, organic disease of the heart, and intestinal torpor, the cerebral vessels are probably in a state of hypersenia. Cerebral ansenia, from loss of blood and deficient vital power, may equally bring on these fits. Convaisions may arise when the urine is albuminous from desquantative rephritis, as in searlet feror, or in measles and small-pox, where the blood is poisoned, and the renal organs cannot eliminate their morbid products.

One peculiar form of convulsions in children is that known as oclampsia nuture or salarm convulsions, because it resembles the obeliance of an Oriental before his superior. It consists of a bonding of the head and body forwards with great rapidity for a certain period, when it crosses. During the time the child seems be wildered, but as soon as the convulsions cease its intellect becomes clear. While they are present the mental and bodily health seem impaired, but no permanent effect in either has been observed. They are not associated with any known changes in the nervos system. They may, however, in certain cases, he the precursor of epilepsy, especially if they are persistent.

Terminations.—Death may be due to asphyxia from the violesce of the seizure, or from shock and syncope, but recovery is usual Dr. West says: "Where the convulsions recur rapidly the prognosis is exceedingly bad, and this is worse in children of three or four years old than in young infants, an indicating a greater disterhance, and one less likely to pass away." He goes on to say, "Far less hopeless are cases, with which we also most orgasionally, of the exceedingly frequent recurrence of convulsions, five, ten, or more taking place every day, for days or weeks together. Such attacks are soldon or never met with after the completion of dentition. The danger to life seems to lessen with the frequency of their recurrence, but there is danger less they should end by their becoming habitual; while, further, there seems to be a very decided relation between the liability to convulsions in early infancy, and the development of epilepsy in subsequent childhood."

Mobid Anatomy.-After death dissection discloses congestion of the brain and membranes, effusion into the ventricles or sac of the arachnold, and homorrhogic points may sometimes be noticed on section of the homispheres; congestion of the spinal cord is also present. These morbid changes are the consequences of the convalsions; just as they occur in epilepsy, they are not the cause, but the result of the unilady. In a single paroxysm such lesions are of no material importance, but where the convulsions reparfrequently, then the change that takes place in the cerebral tissies may result in such a degree of congestion or extravasation as to end in some paralytic affection. Anatomical Issues cannot, however, be invariably discovered on the most careful dissection, and when they are found they appear to be rather a consequence than a cause of the seizure. It should not be forgotten that convulsions are not incompatible with an ansenic state of the bealm.

Transcent.—This does not differ materially from that of epilepsy and some other allied disorders, but convulsions cannot be dealt with alike in all cases. The first step is to assertain, if possible, their cause, before aiming at their removal. In the seizure the child should be surrounded by pure air, and any clothes that interfere with the circulation should be at once removed. If it manot smallow, an ensure should be administered, so as to clear the bowels of any source of irritation that may be lurking in them. A mustard possible may also be applied to the extremities. Placing the child at once in a warm both, so as to excite the cutaneous circulation and relieve internal congestion, is a

^{*} West, on Diseases of Industry and Childhood, 1850, p. 194.

common and useful penetice, whilst cold water is poured over the bend and face at the same time. For the treatment of recurring convulsions, the late Sir James Simpson strongly advocated the use of chloroform inhalations. Dr. Wilks also speaks favorably of the practice. "In those cases where the whole body is constantly distorted, to the great distress of the mother, chloroform will cause the movements instantly to cease, and sometimes with their arrest the child may fall into an apparent sleep. I have given it in many cases with the greatest advantage and relief."s It is not necessary to keep the child deeply assesthetized, but just to administer it when each fit is threatening. When the paraxysm has subsided, the gums should be lanced if tense; and if the subse is good and there is athenic excitoment, a grain of calonel on the back of the tongue may be needed, so as to rouse the liver and small intestines to freer action. In the cases of strong and robust children, where the signs of active hypersemia are present, one or two leeches may be applied behind the ear or on the temple.

To ward off a recurrence of the fits in the intervals, brouble of potassium or ammonium will be necessary to ealm the nervous contres, and it may be well sometimes to combine with it a few grains of hydrate of chloral if there is sleeplessness. Children bear hydrate of chloral well. "Given in a dose sufficient to induce sound sleep of some hours, the convulsions cease, and often do not recur when the child wakes. If the child cannot swallow, five grains given by the rectum soon induce a deep sleep, and the convulsions then cease, at least temporarily."

When the convulsions depend upon toximic causes, as from the scarlatinal poison, the lowels must be kept freely open, and climimation encouraged. Above all, nitrogenous food should not be included in where uramia is dreaded. If there are worms in the bowels, such remedies as ald their expulsion must be had recourse to.

After the constion of the fits, red-liver-oil and some preparation of iron, as the syrup of the hypophosphite, may be needed, whilst a sedative should be given at bedtime to calm the nervous system and to promote sleep.

Night Terrors.—A child who suffers from this affection generally goes to bed quite well, and after falling soundly asleep, wakes up

^{*} Diseases of the Nervous System, 1878, p. 140.

⁺ Hundbook of Therapeutics, by S. Ringer, M.D., 5th edit., p. 271.

in great alarm in the course of an hour or two, screaming in the most terrified manner. The child fails to recognize the nurse, and refuses to be appeared. It has probably been dreaming that a rat is on the bed, or that it is pursued by a savage dog or other animal, from which it cannot escape. After a time the nurse or parents succeed in pacifying the child by parting it and carrying it up and down the room. Then it falls off to sleep tranquilty, and wakes up as well as usual. Sometimes there is no recollection whatever in the morning of what had occurred during the paroxysm of terror. It is consciutory to parents to be assured of the harmlessness of these attacks.

Cours.-These are chiefly indigestion and constitution, but Sarrhos and dontition are also espable of exciting an attack. Worms, injudicious feeding, and bereditary syphills may provoke it. Dr. West relates the case of a boy who had "night terrors" for a year before cutting his first molar teeth." Some seixures would appear to be of an epileptic nature, t and others are allied to hystoria. It seems certain that weakly and pervous children are most prene to suffer. These terrors are sometimes traceable to the cruelty of nurses, who frighten children, and create a fear of being in the dark. Overwork at school is another cause, of which the following appears to be an example: A boy, 12 years of age, of auxious and nervous temporament, was brought to me in 1879, who, four years previously, was seized with somnambulism and "night terrors;" after being askep for three-quarters of an hour he would wake up and get out of bed, then walk out of the room, and if at all interfered with would shriek and become very violont; when his father and mother came into the room he knew them, but seemed terror-stricken, and asked for their protection. The attacks were attended with cold hands and feet, clammy skin, and a thumping action of the heart. When away from home he never had any seizure. A year before I saw him he had several attacks whilst his examination at school was going on, and there was some evidence to show that his brain had become irritable and exbausted. The urine contained phosphates; the motions were large and contive : the abdomen was full and hard.

Diognosis.-These nocturnal seizures make friends anxious, fear-

^{*} Discuss of Infrary and Childhood, 1859, p. 238.

[†] See Chap, XLIII, p. 188, On Epslepsy.

² Hamilfield Jones, up. cit., p. 852.

ing that some cerebral affection may be impending, but if the attacks recur from time to time, yet each morning finds the child free from headache, and there is no intolerance of light or sound, no drownness or staper, and, moreover, the pulse is quiet and regular, and the belly hard and of normal shape, then we are correct in attributing the symptoms to sympathetic disturbance in the abdominal organs.

Trestocal.—In the management of this peculiar state, the digestive functions should be carefully regulated, and all sources of irritation removed from the intestinal canal, by mild specients of soda, rhubarb, and taraxacum (Form. 19-26), after which, brounds of potassium to allay nervous excitement, and iron to restore the strength, will be required. The room should have a light in it, and the nurse or the mother be near when the child areaks frightened. Mental discipline is most important. The child requires to be treated with kindness, yet firmness, and if old exough, reasoned with on the nature of his ailment. He should be treight not to give way to every impulse, or to become petulant on slight provocation.

Master disorder is much less frequent in children than it is in adults, still instances now and then occur, and the practitioner ought to be acquainted with the synoptoms and the forms it may assume. Cases are recorded in which neute manin was set up by the examthemata, typicol fever, and corebral tumors.

Melancholis is a state of mental depression occasionally met with in delicate children whose effective has been defective, and whose parents are moriod or hereditarily necrous. Steiner nontions the case of a boy, six years of age, whose only playmate, his sister, died of tubercular meningitis. He grow melancholy, lost his appetite and sleep, and was termented with the idea that he must die soon. This sad condition lasted two years, when he recovered.* In the adult, cases of mental shock are recorded, the death of one sister being soon followed by that of the other; and the death of one twin adult so affected the other that he has suecumbed to the same disease in a few weeks.?

Nervous and hysterical sympless in boys sometimes occur, just as they do in girls and young women, owing to some unhealthy morbid condition of the nervous system. Dr. Wilks relates the

^{*} Steiner's Disease of Children, by Larson Tain, 1874, p. 57.

⁺ Diseases of the Nervous System, by S. Willos, M.D., 1878, p. 198.

mise of a boy who said he was paralyzed, and that he could neither see nor hear. When it was proposed to apply a red-hot iron up and down his spine, he got up and escaped at the door.* A norbid excitability of the nervous system shows itself in attacks like croup, anorexia, hyperesthesia, nervous dyspuna, and the like.

Crefolism is a very populiar disease allied to idiory. It is an epidentic affection which prevails in Alpine districts, more espeshilly among the inhabitants of some parts of Switzerland, the Pyrences, and the Tyrol. But it is met with in all quarters of the globs, in the Histolayas, Chinese Tartary, Madagascar, the Rocky Mountains of North America, and in a small proportion of cases in Derloyshire, Somersetshire, and some parts of Yorkshire. "It is however, most common in shut-up valleys, and has a close connextion with goitre. Nowhere does cretinism occur where goitre is absent, but gottre may occur where cretinism is unknown or rare." It is commonly aerompanied by an enormous goitre, and is usually congenital. Cretins appear to escape the ordinary ailments of childhood, but they are liable to discuses of the nervous system, so convulsions, hydrocephalus, aethma, and apoplexy. Rickets ending in lameness is a frequent complication.; The cretin is so deliased, and his habits are so low and disgusting, that he is hardly raised above the animals that surround him. He is obstinate, malicious, and sensual. Cretinism is a species of idiocy, accompanied by small stature, mostly under four feet, large and square head, vacancy, and want of expression. The sufferer from this disease is sometimes blind or deaf and damb. Life may extotal total age. Dr. Güggenbuhl, in 1841, established a hospital in the Canton of Berne, for the purpose of educating these poor creatures; and the experiment was attended with some considerable success.

Hiery.—An idiot may be defined as a person of unsound mind, whose moral and intellectual faculties are more or less destroyed, or have never been perfectly developed. Drs. Bucknill and Tuke define idiocy as "a congenital deficiency of the mental powers." In Dr. Iroland gives the following definition: "Idiocy is mental deficiency or extreme stupidity, depending upon malnutrition or

^{*} Dp. rist. pt. 78%.

⁴ Psychological Medicine, 3d edit., 1874, p. 102.

^{2 35}th; p. 192.

disease of the nervous centres, occurring either before birth or hefore the evolution of the mental faculties in chidlood."

It may show itself seen after birth as a consequence of organic disease of the brain. The affection is incurable, though something may be done in the way of discipline and training. Some idiots can scarcely speak, whilst others articulate a few words, and so some extent are expuble of improvement. They are not able to acquire knowledge like other children; the mind remains childish, and the countenance is void of expression and intelligence; the forehead is low, the mouth open, the ears large, the lips are thick and everted, and the teeth are decayed. There is deafness and imperfect articulation, whilst the hands are used awkwardly. The functions of organic and animal life are more or less impaired, nutrition is imperfect, and the motions are frequently passed involuntarily. Idiocy may be associated with stanted growth, riskets, goitre, etc.

The expression of the idiot is good-natured and confiding. Idiocy is frequently seen in the families of those in whom the neurosal tendency has been manifest, by such diseases as epilepsy, insanity, and imberility. Dr. Ireland says, "Idiocy is of all mental derangements the most frequently propagated by descent." Of 2000 cases, 45 per cent, presented well-marked neuroses in one or both

parents.

"Out of 420 cases of congenital islicey examined, some information was obtained respecting the condition of the progenitors of 250. Now, in all these 250 cases, saw only four, it is found that one or the other, or both, of the immediate progenitors of the unfortunate sufferers had, in some way, widely departed from the normal condition of health, or violated the natural law. That is to say, one or the other, or both of them, were very unhealthy or screfulous; or they were hereditarily predisposed to affections of the brain, causing insanity; or they had intermurried with blood relatives; or they had been intemperate, or had been guilty of sensual excesses which impaired their constitutions."

Backwardwess.—There are some defective children who cannot be truly denominated idiots. They are slow to learn; "back-

Mincy and Imbendity, 1877, p. 1.

[†] Op. olt., p. 17.

¹ Belt, Mod. Jour., Oct. 11th, 1870.

Export of Commissioners of Massachusetts on the Causes of Liferry, 1948, p. 3.

ward " is the term used here, "sujons arrabes" as the Fronch term it; they cannot keep pace with other children at school, at least when small. Some of them, however, brighten up considerably when the pubertal changes are completed, and in ecdinary matters can take their part in life fairly well, but they are incapable of any great mental effort. Others are not so fortunate, and continuous spicuously defective throughout the whole of life. Where the parents possess sufficient means, it is well to place these children under skilled supervision, as the training to which they are subjected is of the most vital importance to them.

Inhedity is a term used to denote a minor degree of mental deficiency than iddeey (Bucknill and Tuke). Some imbecous know those about them; they are affectionate, and are capable of taking care of themselves, but passionate and inclined to theft. Others are shread and witty, joinlar in their conversation, and came much amusement. There are those again who are dangerous to society, liable to commit acts of naurder or incendiarism.

"At a very early age the functions of the brain—at least in regard to its intellectual operations—appear to have stopped; hence we see a school full of grown-up boys and girls, sometimes of the age of eighteen or twenty, no more capable of taking care of themselves than children of three or four. They cannot use their hands in any ordinary operation; sometimes they do not know the way to cat with a kulfe and fork, and as a rule, the newcomers are utterly incapable of dressing or andressing themseires. Their very actions are those of little children; their tmotions and fears, their joys and sorrows, remind us most forcibly of those we witness in a nursery of little ones."

Treatment of Micry and Labrality.—A great deal can be done for these unfortunate children in the way of education. Institutions like Earlswood and Normansfield in this country, and many in the United States, fully prove that the treatment pursued there has been attended with the best results. The aim should be to put the locilly health into the best possible state, and then, by a specially moral and judicious occurse of teaching, to improve the mental condition.

Parents in the upper walks of life are frequently disinclined to part with children thus afflicted, but it will be well to strongly advise the placing of such ruses under proper fraining, as it is

^{*} Restigation of Inquity, by Andrew Wynter, M.D., 1875, p. 147.

impossible to obtain for them at home the same beneficial influences as they would from those who have made the subject a study. Moreover, it will always be of great importance to isolate an idictic child from the other children of a family, as the bealthy will ordinarily tense and tyraneize over the weak, whilst the contact with imbedility cannot be otherwise than detrimental to the more fully developed minds.

Thus may be active or arterial, passive or venous; active congestion being that in which an actually larger quantity of blood is supplied to the brain and its membranes, and passive congestion existing where there is no increase in the supply, but an impediment to the return of the blood from the brain and its membranes to the right side of the beart. It occurs in so many discuss both of functional and organic origin, that it must be viewed more as a symptom than anything else. Still, I believe it to be an independent affection, an uncomplicated condition, which does occur now and then in infants and young children.

The amount of cerebral congestion varies a good deal in different cases. The membranes of the brain are almost always congested at the same time, as the same causes act upon both parts. There is a simple post-meetern hyperemia, which occurs from gravitation of the blood to the lowest level, and is seen after death from febrile diseases where the blood remains unusually fluid. Post-mortem examination shows the vessels of the brain to be full and encemously congested in some cases, where this has not been suspected during life. There may have been no stoper,

so headache, no convulsions—no symptoms, in fact, to call attention to this morbid state. When congestion is severe, not only is the brain more turgid, but its volume is netually increased. The gray matter appears dark red or violet, and where the hypersenia has been severe, as in infants soon after birth, the white matter may appear almost as dark as the gray. On outting through the brain-substance, drops of blood are seen to coze in profusion from numerous small points, which are the mouths of open bloodyeasels.

Grazz-Active congestion may occur in hypertrophy of the left ventricle, in connection with valvular disease, which is seen in children after rhoumatic fover. Whatever excites the circulation propels more blood to the brain, and overfills the vescels and simuse. If it he vitiated by the absorption of the scarlation or multipox poison, we have a most efficient cause of congestion. How far again may not cerebral congestion be a consequence of the convulsive paroxysm rather than a cause, due in part to some disturbance of the nervous system, which deranges the cerebral circulation? A child three years of age, who was in good braith, was taken out in extremely cold weather, and when brought hame was drowsy, and the extremities were cold. It soon relapsed into un unconscious state and died, death being precoded by a convulsion. No post-meeten examination could be obtained, but the cordinal symptoms were in all probability due in great measure to congestion of the brain and its membranes. This pathological state, too, probably exists in the preliminary stage of many diseases, as small pox and scarlet fever. Congestion of the brain occurs in the disturbance mused by dentition, injuries of the head, or exposure to beat, and also in consequence of violent fits of coughing, as in whooping-cough, and from severe or prolonged vomiting.

Symptons.—The symptoms of cerebral congestion are generally those of increased excitability. There is febrile disturbance, beat of head, quick pulse, and disinclination to encounter the light. If the child is old enough it complains of pain in the head, and is fretfel and irritable, any soise or excitoment in the room aggratating the symptoms. Sleep is disturbed by sudden starts and muscular twitchings. The bowels are generally constituted, and tickness and headache often procede the outlevak for some days. Such symptoms as these are common enough during dentition, and under careful diet and unitable medicines they pass off; but when they are present we are never certain what the issue may be; not infrequently a fit of convulsions ensues, consequent on the sersbral congestion. On the other hand, the case may drag on, and the child, though recovering from the more acute symptoms, becomes fistless and torpid; it ceases to have an interest in persons and things; it often vendts its food, and the pulse is habitually quickened. We apprehend the supervention of meningitis, though the temperature may be scarcely if at all elevated till a later stage.* The case continues, and either a convulsion or droughous, succeeded by heavy restless sleep and commune symptoms, precedes doubt. In other cases the principal symptoms are delusions or hallocinations, and the severest degree of cerebral congestion causes symptoms of apoplexy.

In 1863 and 1864 I had under my care two children of the same family, aged respectively two and three years. After being taken out in very cold weather they were seized with symptoms of combral congestion, followed by drowshuess and collapse, with coldness of the extremities. The symptoms were alarming for a time, but a warm both and a stimulant in both cases brought about recovery. The children were both well till the exposure, and they have since grown up strong. On the whole the disease is not very fatal, but repeated attacks of it lead to the transmission of scrum and solems of the brain, which may result in imbecility or paralysis.

Treatment.—This is similar to that which has been recommended in simple meningitis. In severe cases that are seen early, where the pulse is strong, leaches to the scalp may be necessary. Dr. West records the case of a little girl two years of age, who was seized with convulsions and congestion of the brain preceding the scuption of small-pox. He bled to three camees, then applied eight leaches to the head, and gave active cathactics without much benefit. The restlessness, equinting, and rolling of the head continued, notwithstanding he applied eight more leaches to the bead, which "bled profusely, and the bleeding was followed by great diminution in the convulsive movements." The cruptive disease ran its course favorably, and the child recovered. Bleedletting, as a raie, will not be necessary. It is important to be extremely eautious in the abstraction of blood, for young children bear the

See Chap. NLII, pp. 564 and 572.

Ou the Disease of Salamy and Childhood, 1816, p. 40,

loss of it badly, and we commit a serious error if we draw too much. When the symptoms are relieved we should at once arrest the bleeding, but if they return, and the head is hot, or there is drow siness, convulsion, or threatening come, then we must repeat the bleeding; but never unless the strength of the child soons to warrant it. A dose of calcarel to act as a purgative is often advisible. The syrup of senna, or the sulphate of magnisia and nitrate of potash mixture (Form. 8) will be necessary, and if these are not offertual then an active enema may be needed. Starvation or little rise than cold water to drink, must be enforced. The head should be shaved and elevated, and cold applications applied and enutionally proceeded with. The ice-cap is excellent, and where this is not at hand, pounded ice, applied in two bladders, and placed one on either sade of the head, behind the rars, will be advisable. The patient's room should be dark, quiet, and cool. If the head symptoms are owing to the exanthemata, as soon as the emption of the particular disease has appeared they usually subside; and the case from that time pursues a favorable course. When they appear to be the consequence of indigestion, or an overloaded state of the stomack, they pass away as suon as this organ is once again put in right working order; but the cause must be ascertained lest we commit an error in management.

In these cases, the first point to be attended to is the tousing of the artery, which must be our guide. If it is full and incompressible then it is clear that our treatment must be directed towards the lowering of this arterial tension. To dilate the arterioles of the rest of the body is one means towards attaining this end; to shetract blood is another. Formerly the practice would have been be bleed the child, or to apply feeches, probably also to purge freely. Now we would prefer to deplete the congestive brain by vascular depressants. Rasori's plan of the free administration of tartagated antimony held its ground for many years, but disastrous tensoquences often resulted from the free use of it. Then comes the treatment of Fleming, viz., that of lowering the heart's action and dilating the arterioles by the exhibition of acomite. Acouste lawers the heart's action at the same time that it dilates the arterioles, and thus lowers arterial tension-otherwise the blood pressure in the arteries." It is well, also, to act freely on the lowels, and therefore a purgative should be added to the vascular

⁸ See The Action of Acordic, Chap. XI, p. 128, and Chap. XXXVIII, p. 460.

depresent. This is the more necessary as constitution is frequently associated with the head affections of children. Purgation ought to be maintained until all the symptoms of congestion have passed away. When the congestion is accompanied by chronic spasses, heat of head, and injection of the conjunctive, then it is well to give bromide of potassium, or even chloral hydrate.

Apoplezy, or cerebral Annershops, sometimes occurs in infancy and early life. Excessive congretion of the sinuses of the brain, and of the vessels which ramify over its surface, takes place, and this is followed by rupture. When the brain is edited, numerous small red spots are seen in all directions, from which blood onces, and the white substance has in some cases a pale pinkish tings. The hemorrhage may take place into the cavity of the amelandd (accessingly), or the substance of the brain, or very rarely into the ventricles (credeal).

This affection is most common during the first few weeks of life, but it may some on during many discuses, as whooping-cough, convulvious, and any complaint in which there is a strain thrown upon the repelval ressels, or the blood is imposed in its return from the head, as in congenital heart discuse, or affections of the bronchial glands pressing upon the large vessels. It is possible, too, that the loan may have sustained some injury during parturition, when the head in its slow transit through the polvis has been subjected to long-continued pressure, the face and the scalp attesting what has taken place within the skull. After a protracted continuent, or where the mother has been subject to pureperal columpsis, the child may be born with hemiplegia of the face, arm, and log, showing that hemorrhage has taken place into the corpus striatum.

The condition of the cerebral vessels in early life is entirely different to that of the adult; the arteries being clastic and yielding, congestion is favored, but rupture is less likely to occur, because their coats have not undergone the degenerative changes which are common in mature life. It is true that the coats of the cerebral arteries are very thin, since, owing to the unyielding structure of the cranium which encapsules the brain, they are more protected against blood pressure than in softer parts of the body, where the arteries can expand to a greater extent. Morbid conditions, such as nonsmal softening of the substance of the brain, may allow of expansion of its thin-valled arteries to a dangerous extent. Fits of convulsion, attacks of violent coughing, which produce enormous fulness of the chief vessels of the brain, rarely lead to rupters, but the smaller vessels may give may, and cause homorrhaps. The hemorrhage varies in extent. When there are a few dots, the size of a pin's head, it is termed capillary homorrhage.

The symptoms which denote this condition vary according to the soldenness or gradual approach of the science. It would be impossible to enumerate conclusive symptoms. When sudden, there are stuper and convulsions. "The sudden occurrence of siokest convulsions, and their frequent return, alternating with spassodic contraction of the fingers and toes in the intervals, appear to be the most frequent indications of the efficient of blood upon the surface of the brain."

When an extravasation is small, the symptoms may be obscure or even absent; but when large, and it occurs in the substance of He brain, or in the cavity of the arachnoid, the usual symptoms of compression may be looked for. The child lies in an unconacions state, with a dusky face and contracted pupils, the eves are dim, the pulse small and slow, the respiration is irregular and usually slow and superficial. Youiting is often present, and the howels may be constiputed or loose. A severe attack of serobral assnorthage is always accompanied with involuntary evacuation of the urine and faces. If the child is fed at the breast, it loses its hold of the nipple, and cannot retain it in the mouth. In larger effusions in older children, the attack is usually sublen; beadarhs, restlesoness, and disturbed sleep, unconsciousness, loss of speech, convulsions, and irregular breathing, may be the precursors of death. In the commencement of the attack, the temperature generally falls to 96° or 95°, from irritation of the controlling centres of heat production; while later on, more especially when the blood breaks into the lateral ventricles, the temperature begins to rise. Where this rise is sudden and extentive, us when the mercury runs up to 103° or 105° in a few bours, it is a sure sign of impending collapse and death-

Transcent.—When the case is seen early, leaches to the head have been recommended, but, as a raie, this will be rarely necessary, a dose of calomel and purgative enemats being usually active enough for a child. Under this mode of treatment the symptoms

^{*} West, On the Domes of Infrary and Children 1859, p. 41.

may disappear. The head should be shared and cold applied. If the gums are distended they should be lauced.

Chorks may be accepted as one of the most singular of the numerous disorders which affect the nervous system. It is substantially allied in some respects to other neurosal conditions; but it is so variable and capricions in its manifestations that it may be elinically recognized as possessing psculiar and independent phenomena, which distinguish it from all other affectious.

Chorea is a functional derangement of the motor nerves, causing irregular movements of the muscles, and influencing voluntary action. It is a common disorder in nervous and sensitive children, from the greater excitability of the nerve-cells in youth. It is not accompanied by fever. With it there is no defect of conscious new or relition, as is the case with epilepsy.

Symptoms.—The discuss occasionally crosps on slowly and insidionally, the child being out of health for some time before any chorcic movement is observed. The first symptoms are restlessnose and imbility to sit still for even a short time, and the parents not musturally ascribe this to a fidgety habit, which may and ought to be controlled by discipline. In other cases the discuss begins with a slight twitching of the muscles of the face, the patient putting the mouth into the most grotesque forms and contections, as if mocking or "making mouths" at you. In other instances the facial muscles escape and the tremulous agitation is confined to the limbs. When asked to put out the tongue it is accomplished suddenly, or with a peculiar rolling motion, and then withdrawn in like manner; but it is sometimes protruded with case, and kept out for a short time. Eating and swallowing are performed with difficulty, and the food drops from the mouth because there is no control over the tongue and pluryngeal muscles. The speech is often thick and hesitating, and the child twists and turns its mouth and head in the endeavor to get out a sentence. There is a general enwillingness to utter a word, and the tongue is sometimes bitten in the attempt to speak. After a time the disease extends to one or both arms, and later on to the legs, and thus all the voluntary muscles become implicated in spasmedic action. The child, if a female, will perpetually pluck at her dress, raise her hand to her head as if to play with her hair, or rapidly put it behind her; she will be noticed at this stage to drop things out of her hand, and to be unable to held or direct her pencil when at school. In walking she leans on one side, drags one leg, or mises it awkwardly. Her walk is a jumping, unsteady, sudden, shuffling kind of gait, as though the joints hung loosely, and she was compelled to put berself together before making the attempt. The manner of locomotion is bulicrous and fantastic in the extreme, the writhing of the shoulders, the careless semi-drunken sway, and the peculiar grimace, or fatultous expression of the features, are all characteristic. The movements cease with sleep and the abolition of consciousness.

In severe cases the patient is unable to stand or walk. If she can manage to walk, she shuffles along in a nervous hesitating manner, as if afmid of falling down every moment. The kness and elbows may be polished from friction, and even the skin abraded; the chin is red, and the lips sometimes bleed from biting said friction against the pillow. So violent are the paroxysms that the back may be arched one moment, and stiff and straightened the next. The speech may be unintelligible, and the emaciation become extreme if the case goes on. The pulse is not accelerated except from debility and nervous agitation. In some cases it is slow, and may not exceed sixty beats a minute in a child thirteen years of age. Irregularity and intermission of the pulse

are often present." The tongue is sometimes forced, the breath foul, and the howels constinuted. The patient is liable to great variation in the progress of the numbely, being sometimes better and sometimes worse. When the attacks are threatening there may be mental irritability, and evidence of spitefulness. In one case that came under my notice a child, whose intellect was below the average, was unable to restrain herself from kicking and biting those about her. In chronic cases, parents can often judge when an attack is threatening, or when the case is becoming worse, from the altered number and disposition of the shild. Timidity, exprice, and wilfulness are noticeable when the intellestunl faculties are disordered, and it is in such cases as these that we may see fits of passion pass into temporary unconscionenss, I have known the symptoms much aggravated by another putient in the same ward practicing these extraordinary movements and mimieries, or suffering from a painful disease which has irritated the child. This is the only explanation I can furnish of a chereis child's temperature going up to 102° for three nights, and falling next day to normal when removed into another word. Sir T. Watson mentions in his lectures that "chorea is liable to be perqugated by a species of contagion, or rather involuntary imitation."

Sometimes the loss of power of co-ordination is so great that the patient cannot pick up an object with the fingers, or seen

group anything with the hand.

In one case under my care the choroic movements were preceded by headache of three months' duration—a disorder which had not previously been experienced. The patient was a girl ten years of ago, who had become very anxious about her studies. This symptom of headache, according to my experience, is exceedingly rare, except as the accompaniment of aniemia and debility. Sir T. Watson has frequently mot with instances of pain in the head in choron; "and in some of them, with pain on that side only of the head which was opposite the agitated limbs."

Choren is very prone to recur, and a child who has had one attack is always exposed to a return at some future period.

Sec a poper by the author, On Neurosal Affections of the Heart in Children, Practitioner, Sept., 1678.

I Principles and Practice of Physic, 4th edit, vol. 1, p. 668.

[!] Op. ci., roll, p. 65%

When the spasmodic movements are unilateral, affecting the limbs of the same side, the patient is said to have "homishoron." When this happens, the right side is oftener affected than the left. Both legs may be affected and only one arm; or one arm alone, whilst the legs are free. In rare cases, one arm and the leg of the apposite side of the body may be involved. When all the voluntary muscles are implicated there is " general charge."

Carolice sourceurs are sometimes present in this affection, and in the early stages of the disorder they are often overlooked. In some cases we may find exaggerated action and impulse of the heart, or a believe normal reduction. When the heart is so affected it is often traceable to rhoumatism. In other cases the heart is healthy, but the nearotic disorder has implicated the cardiac plexus, and produced irregularity in frequency, and deficiency of power; or there are to be discovered merely the evidences of palpitation, with prolongation of the first sound both at apex and base—a soft systolic normar, in fact, which, though often significant of organic change, may happen in some examples of simple anamin and general debility.

Sometimes pulpitation is very severe and violent, and there may be a systolic mitral neurons of dynamic origin, which passes away with the seizure as the general health is restored.

The urine is often found to be of high specific gravity, excessively acid, turbid, and containing an excess of urea, and sometimes phosphates. In the twelve cases I have alinded to below, the highest specific gravity was 1832; there was a copious deposit of whitish lithates in three, phosphates in four, and in the remaining five (which were mild cases) the urine was normal.* In one case under my care the urine contained copious phosphates for five

^{*} In control consecutive come admitted touler my our into the Samuritan Hospital, on were families; the chiest, a girl, was fonction tous of ago, and the principal a boy of seven. Four cases were traced to digits, two followed meades, one areas from load firing and deficient faul, one sequered in a cardwells and arranges of fild, two came on gradually free green debility, one from a bool work and punishment, and one case tourned and dealy, the child falling down in the street in a species of fit, followed by graced chorus. In this case there are a land special marries of long studing, not travalle to phonomises. In six cases the left side was attacked, in there the tight, and is the remaining three the measurements were not more on one side of the body than to the other.

[&]quot;Among cleren chares patients which I moved in my disry, I find only one boy affected,"-Vogel, Discuss of Children, 1874, p. 398.

days in succession, and the specific gravity was never below 1050. During this time the child was taking from eighteen grains to one drachm of sulphate of zine in the twenty four hours. When she took eighty grains in the day, the urine suddenly became leaded with lithates, and the day following, when the zine was reduced, it was normal.

Course.—Age has a great influence on the production of chorse.

Two thirds of all cases occur between the second dentition and
the development of puberty, between five and fifteen years of
age. The influence of sex is also considerable, as girls suffer from
it more than boys, the proportion being about three girls to one
boy.

Among the causes of this affection are to be reckoned defective nutrition, general debility, and nurmin, worms in the intestinal canal, and disorder of the digestive organs. In fact, any circumstances which tend to lower the standard of health in debilitated subjects, such as had air and food, are likely to generate the disease in children of delicate nervous organization. These causes most probably account for the great frequency of chorea among persons angaged in pottery manufacture, as stated by Dr. Arlidge. Tritability of the nervous system is among the most frequent causes, and hence this is assigned as one reason of its frequency in the female sex.) Overanxiety in school-work is another cause.

The Pathology of Choses, Brit. Med. Jones., 1877, vol. iii, p. 799.

^{† &}quot;But though the fact of the greater liability of the mercur to charge is underhood, so that of 775 children suffering from it who were admitted as in at anti-patients at the Children's Hospital, 495, or 64 per cent, were girls; will, not only were all of those children under the age of too, but 66 one of 192 of the number were mader the age of tree."—On Some Describes of the Nervous System in Children's by C. West, M.B., P.R.C.P., 1871, p. 47.

[&]quot;Of 422 over accurring up to twelve years of age, 122 were make, and 300 females. Between the ages of fear and fire the proportion of scales to females was as 6 to 16, and between ten and twelve, as 23 to 81. Again, when charms occurred after polarity, it was among women that it was principally soon; yet as choose was not confined solite sively in lensites, we seek neck the curve in a factor common to both, but expecially interest at prominent in the female." "Crosson Lecture, by J. Benaton Highs, M.D., P.R.S., 1877.

[&]quot;Up to mine years of age the two series against to be equally liable; after this age features become much more liable than makes in the proportion of morely 5 to 2"—Chang, by C. H. C. Radulitis, M.D., Reynolds's System of Medicine, vol. ii, 2d o'bi-p. 155.

[&]quot;The 'closes of childhood' has come largely under my notice at the Sudord Courty Indianary, and drawing my conclusions from cases seen at that institution I see dis-

Nervous disease in the family especially predisposes to it. Hysteria in the mother, or epilepsy in the father; melancholy, suicide, or insanity in the parents, can be frequently traced.

Fright, anger, and injury may also induce chorea. Several cases have come before me in which the disease has been traceable to terror and alarm. One of the worst cases I over saw came on suddenly in a girl, 10 years of age, from seeing a dead person, In another case which came under my notice in February, 1879, a girl, eight years of age, had three severe seizures; the first from grief at the death of a sister; the second from seeing a lady killed in the street; and the third from hearing of the sudden death of her grandfather. Choren sometimes arises during conralescence from acute rheumatism; it is seen in secondary syphilis and other toxic changes in the blood. It may result from embelism in connection with rheumatic endocarditis, but the concarrence of choren with rheumatic fever is not quite so frequent. as is supposed, though it exmost be denied that the rhenmatic constitution is sometimes associated with it." In the twelve cases referred to there was no history of rheumatic fever in any of them, and in a large number of cases I have failed to discover anything more than a casual relationship.

Of 66 cases of chorca observed by Dr. West, 16 were accompanied or preceded by rhoumatic symptoms, and in 11 of these there was a systolic bruit persisting after convalencence in 10. In one of the 16 cases, rhoumatic symptoms and heart disease followed in the course of the chorca; in all the other cases the rhoumatism preceded it. In 2 cases, although there was no rhoumatism present, nor any history of rhoumatism, the heart was the seat of valualer affection when the patients came under observation.

A case of chorea is related by Dr. Althaus, where it came on from maxturbation at fifteen years of age, and after lasting for six years, it because complicated with spilepsy. Arsenic, brouide of potassium, and various perre tonics and solutives failed. Hydrate

posed to fix the age at which it is must frequently met with as being between an analalous years, the generality of race occurring a metal-law tailway between those ages," —On Chebria Charaloge Demokra, by H. Day, M.D., F.B.C.P., Medical Society's Proomlings, vol. iv, p. 85.

^{* &}quot;Cheen is apt to separces in young subjects after the avocation of the febrile distributes in channel is fever where the heart has been implicated."—Riscontinue. by A. R. Garrol, M.D., F.R.S., Beyonda's System of Medicine, 1876, vol. i. p. 221.

¹ West op. ch. p. 52.

of chloral checked the restlessness and general convulsion till the patient got into the habit of taking immolerate doses, and at last died in 1874."

We may sometimes witness choren in children who have been hadly fed, and who have had their health reduced by scarlet fever and measles, and whose pacents are nervous and consumptive. In a case under my care in 1875, with such a history, two children out of a family of four died of convulsions. In a family with whom I was once acquainted, one daughter had severe choren, the other died of convulsions, a son periabed from phthisis, the father hanged himself, and the mother died of paralysis.

(Chorca presents some points of difference when it occurs in old people. The discuse in them appears to be remarkably rare, but to be incurable. The movements of the face and limbs are not so active, and the discuse is more chronic. According to Charcot, obered in old people is an emotional discuse, and is unaccompanied by any cardine lesion. The subject of it often labors under more or less dementia, and it has no connection with rhounatism, like obores in early life.)

Pathalogy.-There are two theories extant, one in which the disease is attributable to embolism, and the other to hypersmin. Both have found able advocates. Dr. Dickinson is opposed to the embolic theory, and it appears to me inconsistent with the history and clinical features of the disorder. Of seven fatal cases in which Dr. Dickinson made post-mortem examinations, he found no plug of fibrin in any of the arteries. Of twenty-two fatal cases which be examined, the frequency of mitral cadocarditis was noticeable.; He believes the disease to consist in hypersenia of the nervous centres, particularly of the corpora striata and thalami optici, and that congestion in the cervical, dorsal, and lumbur portions of the spinal cord is frequently to be detected. Dr. Broudbent has seen "one fatal case of rhoumatic chorea with delirium, in which there was plugging of minute vessels of the lexin with decolorized clots "4 Dr. Hughlings Jackson has met with emboli in the small arteries, and others have seen them in the corpora striata. The slow manner in which the disease so fre-

¹ Innet, Oct. 16th, 1824, p. 361.

quently croeps on, and returns from time to time at uncertain intervals, the occasional sudden disappearance of the disorder, and the sciences being often general instead of onesided, are not consistent with the theory of embelism. Dr. Handfield Jones truly observes, "that there seems no more reason for requiring a demonstrable lision in chorea than in many cases of insunity or delirium tremens, between which and chorea a considerable analogy certainly exists."

In two cases of "canine choren" there was found after death, in one case, a granular and swellen condition of the nerve-cells of the spinal cord, and in the second-case there was seen, in addition, a singlar lesion in the medulla oblongata and cerebellum, while the corpora striata and homispheres were free from it.

When the chorea is associated with temporary loss of consciousness and with convulsive seizures (hysterical or epileptoid), Dr. Gowers thinks the disease may depend on an unstable condition of the nerve-centres, or on imperfect development or nutrition of these centres. He mentions several cases illustrating the association of chorea with epilopsy.

In some fatal cases, evidences of inflammatory lesion have been found in the langs, plears, brain, peritoneum, and spinal cord (applitie), and there have been also noticed hypenemic patches of extravasation in the coats of the north and endocardism, when these did not depend on rheumatism. The chores probably possesses the tendency to so affect the nervous centres as to destroy the balance that normally exists between them and their vascular supply. Perhaps the most frequent change is that of "vegetations," or fibrinous deposit on the valves of the heart. In 14 fatal cases, 18 presented these alterations, and there was scarcely one of them in which the changes could be traced to embolism (Handfield Jones).

Treatment.—Rest in bed is the first and most important step to observe, and with rest alone there is no doubt that many cases recover. Drugs exert only a secondary influence. Where the convulsive movements are incessant, splints softly pudded should be applied to the limbs, and it may be even necessary to cover the

[!] Reit Med Josep, April 6th, 1878, p. 481.

body with cotton-wool to prevent the patient from sustaining bruises and exceptations. It is then advisable to remove any eccentric source of irritation wherever it may exist. If there is feenient matter in the bowels, and constitution, as frequently happens, mild purgatives, such as rhobarb and castor oil, are to be selected. In some cases where the muscular agitation is great, free purging will be followed by rapid improvement, and this preliminary treatment ought never to be omitted if there is any reason to suppose that the intestical tract is disordered. Unhealthy motions, scanty and high-colored urine, demand this treatment." A case of acute chores in a girl of nine, which had lasted a month, is referred to by Dr. Harsifield Jones. The attack was very aggravated. The movements were incessant, and there were sordes on the lips, a bedsore, rapid feelds pulse, and a tendency to sinking. After a dose of scale ferm, a tapeworm seven yards long came away, and in a few days the convulsive movements ceased and the child recovered completely.

To relieve the drynoss of the skin, which is frequent in chores, and to produce moisture, a warm bath at bedrime should be employed, and this has been recommended and adopted both by English and Continental physicians. Sulphur baths have been

highly spoken of by French writers.

Secus cosi has been recommended, but my experience does not enable me to speak in its favor. We do hear of and see cases where two drachms have produced certain physiological effects as dimness of vision and dilatation of the pupil, but I have given sixteen drachms in the space of twenty-four hours without producing any solutive effects whatever; indeed, in the case to which I refer, of chronic choren, the child, aged ten years, was no more affected than if she had taken materially. Dr. West gives similar evidence regarding the use of this drug, and also of herbane and belladonna. He has known them to be tolerated in pois-noos doses without any result for good or evil.‡ Curura is another remedy.§

B. Poline sulphut., ge a.
Pulse, shee, gr, iv.—M.
To be taken in the early exercise. For a child ten years of age.

On Franciscal Nervous Distribute, 1971, p. 255. † On ein, p. 72

I Dr. Drammanh, of Newsonthean-Tyres, newcoded in carring an administrate of general chance in a girl seven years of age, by the submittaneous injection of caram-

Dr. Pulmont found that gr. * of hyoscyamia augmented to gr.

‡ twice a day, proved very efficacions in chronic cases in adults,
the improvement usually setting in in the course of eight or nine
days. Symptoms of innoxication were occasionally observed, indicated by dryness of the mouth and dilatation of pupils.*

Chloral hydrate has been recommended in large doses in violent shores.† The principle of treatment was to give thirty grains, and to repeat the dose, or half of it, if the patient did not obtain ten hours' sound sleep in the twenty-four hours. On waking, a second dose was given in proportion to the ascertained effect, but always less than the first. On waking again another dose less

He commenced with an expected valuation of go. In the two dates, increasing the date on the third due to gr. 2s and the next day to go. 4s on the fifth day to gr. 4, and on the sink day to gr. 1, by which time the patient had recovered complete power over the polarizety mascles. Two days later gr. I was administrated, and then there was no neura. (Brit. Med. Josepa, Jana 18th, 1978, p. 657.) In a chronic case of closeca, which was admirted into the Samarinas Hospital under my care, in October, 1818, I determined to my the current. The parient was a girl elemen years of age, and had been under any care on three previous occasions for the same disease. There em its communication of the arms and lags, and it was necessary to keep her in bod. The bear's action was eather than ping and excited, and there was a soft systelic besis twee the spez. After taking hypophrophies of ends and iron, so well so coldiner oil the was not munifiedly better, and my excitement or talking would make her very felgety, and increase the manchiar movements. On the 19th of October I injected into the right florestru gr. 45 of curars with the following effect: 19th -- 10 A.m., to effect; 11 a.M., gr. A injected; 2.50 s.M., no charge, pulse 32, gr. A injected; 6.45, soon the injection she has been much quinter, and fying perfectly will with complete remanual over the limbs, pulse 30, inclined to alone. 17th -She had an excellent night, and slept leaver than she had done for uson time past, but agitation was retenting in the ation, and I now expected gr. To at 18,46; at 8.45, as there was no further improvement, I injected gr. fa. 18th.-Sleps well quite steady in army and legs; aspend Prof. 18th -2 s.it, she had renaised polet; pr. /4 injected. 20th - Ne injection med, but after 2 p.m. the limbs become more optioned, and the sums local but face were more in action. Elst. The mouth, hands, and legs were mixing more. The effect of the curars has been to keep her spilet for twenty four hours, and then it passed off. I. must what that the strug partially answered my expertations, and I should be disposed to employ it again when the agitation it good, because it controlled the movements, and council meither benefacing, nickness, nor any anglessant symptoms. Our difficulty in To slice which the injection causes. I now gave sulphate of size, beginning with three grains three times a day, and gradually increasing to fony grains twice a day, stilling curring sickness, names, or loss of appeths. The effect of this trentment was It came a great deposit of phosphates in the arise, but the remedy in those large door did more good thus may other that was complayed.

* Burl. Génér, Thérapestique, Aug. 3d, 1975.—Quoted from the Proctationer, Octables, 1876.

¹ Prantitioner, March, 1877, p. 170. By Bobert Bridges, M.B., Oxon.

than the second, and so on till the amount of sleep had been obtained, when the chloral was discontinued till the next night. Of two patients so treated, aged 18 and 20, one was completely cared in our day, and the other on the fourth day. In a case of acute choren in a girl, aged nine, I found five grains every night produce most tranquil sleep, and it was not necessary to continue it after one week. In another case, a girl of 13, took ten grains every two hours at first, and afterwards every four hours. The affects were to procure sound sleep, which she had not obtained for a week before admission into hospital, to raise a small and weak pulse of 64 to 76, and to calm the muscular movements. Good diet, and four ounces of sherry, were given daily. When sleep was obtained, the cure was occupieted with iron, and large does of sulphate of zinc.

There is no question whatever that hydrate of chloral is a valuable remedy in some cases of choren, particularly in those where vascular excitement is present, and the pulse is good. Dr. Althaus considers that the theory of chorea is explained by active hypersmis of the corpora striate, and the parts surrounding the fissure of Sylvins, and that the beneficial action of hydrate of chloral is to be attributed to the ansenia which it produces in these structures. Its dangers as a depressant are nothing compared to the repose and rest which it insures to the nervous system, lessening as it does in suitable doses the extreme agitation of the limbs, and the violence of the chorcic movements. Sleep so obtained gives the necessary time for requir to the overexcited parts, and will be found to succeed when morphia yields no result. The patient makes able to swallow food, which he may not have done for weeks or months. If then there is delirium or sleeple-ness, chloral, opinia, or morphia, to allay mental excitement and procure rost, will be needed.

In some cases, where the discuse has lasted a very long time, the patient passes into that stage of chronic choren or agitation which is likely to become permanent, and there is no further prospect of benefit from treatment. The only thing to be done in these cases is to maintain as far as possible the general health, and to avoid the strain of school-work; and as puberty is reached the discuss may be thrown off altogether. Bearing in mind that the discuss is one which rapidly induces exhaustion, the constant supply of natritious food, easy of digestion, is importatively domainled. The

free employment, too, of stimulants may be necessary to support the nervous waste. I found the liberal use of brandy prove of great benefit to a girl, eight years of ago, who was much exhausted from perpetual agitation of the limbs.

Iros is one of the best remedies we possess in chorea, and mild cases, especially if there is anomia, often yield to it. Where the movements are slight, some preparation of iron may be given alone, and most of such cases will be cared by it. When the movements are frequent, the addition of bromide of potassism is an excellent formula. The bromide may be combined in these cases with the summedio-citrate of iron, the syrup of phosphate of iron, or the citrate of iron and quinine. The syrup of the ledide of iron is a preparation very highly recommended by some authorities. It was first proposed by the late Dr. Barlow, and given by him with great excesses.

Aracuic is a valuable remedy, improving nutrition and acting as an admirable tonic. Children bear comparatively much larger does of this drug than adults, five minims being generally the relatinum dose. Several cases have appeared to me to yield to amenic when given in plain water, and there is certainly evidence to show that it is a very efficacions drug when continued long enough and in sufficient quantities, small doses sometimes failing when large succeed. Dr. Ringer says, that "in simple uncomplicated cases of shoren, areenic is by far the best remedy," Dr. Beglis, after an experience of nearly thirty years, never knew this remedy to fall. Few physicians can, I think, speak in such enthusiastic terms of it. Although in my hands it has failed over and over again, I am quite ready to admit that it sometimes proves successful after other drugs have been tried in vain, if given in sufficient doses. A chorcic girl, nine years of age, who was under my care in 1880, took ten minims three times a day for twenty-three successive days, when recovery was complete. Fiveminim doses did no good whatever. Where amenda is present, the citrate of from and quinine, or the ammonio-citrate of from, or steel wine, may be combined with the arsenic.

Structure has been employed by Trousseau, and as a nerve tonic it is rational to suppose that it will prove serviceable in certain cases. But its tendency to cause twitching of the muscles, which

^{*} Bandback of Theraperties, 4th eds., p. 260.

[#] Contributions to Practical Medicine, 1892, p. 99.

it will do in some cases, even in very small doses, readers it a doubtful remedy in this affection.

Sulphate of Zine - I have given this drug in doses of from one to five grains three times a day, and continued it for a week without producing any effect, and the remedy so repeatedly disappointed me that for some time I council to employ it. This most likely arose from giving it in too small a dose. Sir T. Watson gave it successfully in ten-grain doses three times a day in a servercase which had resisted other remedies. There can be no doubt that zinc sometimes succeeds where iron and other remodies fall, In prescribing it, the dose should not exceed a grain three times a day to begin with, and should gradually be increased till there is musea or vomiting, or an amelioration of the symptoms. In a chronic case, which was temporarily relieved by the hypotermic injection of curara, I began with two grain doses twice a day, increasing the dess daily, till on the ninth day, the girl, seven years of age, was taking eighteen grains. For the first time this controlled the agitation, improved her voice and appearance, and caused no sickness. On the feath day, she took twenty grains three times a day, and on the twelfth day forty gmins twice a day, without causing the least unpleasant symptom. The heart, which on admission was rather unsteady, with a soft apex built (owing to detaility), became quiet and regular, and the mormur entirely disappeared. Among the chief signs of improvement was the strength of her voice, the case with which she answered questions, and the control she had over the tengue and facial muscles. In another similar case no benefit resulted, and the patient only became a little sick after taking ninety-six grains in one day.

Sulphate of copper is used by Italian physicians for chorea.

Phophorus in combination with iron is a good nervine toris, and when persistent amends is present it should be employed. It often takes the place, or even supersedes the use of iron, restoring the tone of the nervous functions, and improving the quality of the blood. Dr. Radeliffe speaks highly of the hypophosphite of soda. He says, "I have given for some time from five to eight grains, three times a day, of the hypophosphite of soda to children in cases of chorea, without any harm certainly, and, as I think, with unmistakable benefit, and I have not yet found any reason to change this practice for another." In ordinary cases be also gives cod-liver oil with the hypophosphite of soda, and adds cam

phor, or carbonate of ammonia, or both, according to circumstances, Of sixty cases so treated, the average duration of treatment was under one mouth." I have frequently given, with advantage, five grains of the hypophosphite of lines and one drachm of the symp of phosphate of iron in a tablespoonful of water twice a day.

Quinine and bark are useful in their turn, and cod liver oil is

one of the best remedies.

I have never employed tarturated untimony in any dose, nor can I see a remon for supposing that it could prove of real utility. It seems a remody likely to do harm from its depressing effect, though cases are recorded in which it has done good. Dr. West has given "as much as nine grains of it in one day for three days together, with to sensible influence on the pulse, no sickness, and no diarrhos, but with very remarkable abstement of the movements."

Finally, sen air, shower-baths, cold-water deacher, gymmatic exercises, are useful in properly selected cases. Galvanization and familization are also to be recommended. A gentle constant current, applied for four or five minutes to the suffering portion of the brain, generally arrests the chorcic movements at once. In bemishores the opposite side of the brain must be gulvanized.

CHAPTER XLVI.

DISEASES OF THE SPINAL COURS.

Servat Innivation. Servan Hamounitain. Servan Massouris: Southern Philology and neutron. Markette: Symptone Course and treatment. Courses servat Massistories (Caraman-servan Favous).

Arvacrioss of the spinal cord are obscure at all ages, and they are more so in young subjects than in adults; for whilst in the latter any impairment of motor power or abnormal sensations would be at once complained of, in the former, serious mischlef might proceed for some time before we are able to detect it.

It must also be admitted that examination of the spinal cord and its membranes after death is most unsatisfactory. The body

^{*} Chara, by C. H. R. Baddide, M.D. Beywilde's System of Medicine, vol. ii, 24 edit., p. 120.

allowed to remain on the buck facilitates the gravitation of blood and fluids into the most depending parts, by which the nervous tissue itself is altered, and the evidences of congestion and offusion, which are hastily attributed to disease, may be entirely due to position. This fact has struck most observers, and rendered an explanation of the changes discovered after death very confusing. and calculated to mislead. "First of all, as regards the muchabused hypersenia, all post-mortem appearances must be excluded as spurious where the body was not placed squa its face immediately after death, and the autopsy was performed later than twenty-four hours after life terminated. Without this progution there will be found in every case, even in the most normal, extenrive post-mortem hypostasis, imbibition of the coloring matter of the Bood, and putrid softening, by which it becomes tetally impossible to establish the previous existence of any actual disease in the modulla spinalis."

Spiral Levisions.—"We have no more right to refuse to spiral irritation the vision to a separate existence, simply on the ground of the want of a known basis of anatomical lesion in the cord, than we have to do the same in acute ascending paralysis, in terany, and many other diseases which betray an equally imperfect knowledge of pathological anatomy."† The symptoms that denote this condition are more or less impairment of motion in the upper or lower extremities, according to the sent or degree of mischief that may be present. There is pain of an obscure character in the corrieal or lumbar region, languor, and failing health. In some cases the pain is sowere enough to simulate disease of the vertebre; there may be tenderness along the spine, and even some pufficess, and the degree of congestion may be sufficient to produce more or less stiffiess of the neck, and pain on moving the head.

Or. West describes the case of a little boy, two and a half years old, who had scribbles of the spisol cord from masturbation; he tottered in his gait, was indisposed to move, and at last almost entirely ceased to walk. When the had practice to which he was addicted was put a stop to, he soon regained his health and the power of walking.

Yogel Dinmer of Unitient, 1871, p. 374.

⁴ Zomecen's Cyclopedia of Malicine, 1878, and aiii, p. 350.

² Director of Delicey and Childhood, 1838, p. 162.

He also relates two other cases in children of four and five years of age. In one case the symptoms began with failing health and stiffness of the neck, succeeded by the head being thrown lack and motionless, pressure over the cervical vertebne gave pain, and the appearance and summer of the patient seemed to point to discuss of the cervical vertebrse. The application of four backes to the back of the neck was followed by sleep, and next morning there was no pain in the head, or tenderness of the spine, and complete power over the muscles of the neck.

In the other case, the child had a fall on her back too days before she was seen by Dr. West. The day following the fall she
was anable to stand or move without support, and had continued
in the same state ever since. There was heat of skin, frequent
pulse, loss of appetite, thirst, and furred tongue; the beweis were
constipated, but the urine was normal. The integuments from
the tenth, to the twelfth dorsal vertebre were pully, and there
were pain and tenderness over the spine in this situation. Capging to four coases over the loins was followed next day by relief
of the pain, and the power of moving her logs more readily. She
recovered in a few days.

Spinal Hemorykage,—Cases of spinal apoplexy in children are on record. "Ev. Abererombio gives a single instance, which recurred under his own observation, in a child aged seven years, in whom, after an illness of three days, death ensued from violent canculsions. A long and very firm congulum of blood was found, external to the cord, extending the whole length of the cervical portion."

Apoplexy of the spinal membrane (like the cord itself) is so rare that Wilks and Moxon have never met with it † Still it occasionally occurs, causing paraplegia and other symptoms, arising from pressure. The symptoms are violent pain in the region of effusion, general convulsions, and speedy death.

Spixel Meningetic.—As the membranes of the brain are liable to acute and chronic inflammation, so are those that invest the spixal ord. Spinal meningitis appears to be more common in new-born infants than in adults, and is considered to be pyremic. "Billard found that in thirty cases of convulsions there was meningitis of

^{*} Jeses and Secretary's Puthological Amsterry, by Physic, 1875, p. 202.

Periological Amatomy, 1870, p. 246.

the cord in twenty, only six of which presented inflammation of the corobral meninges."

Acute inflammation of the dura-arachnoid (peeks accompany) is rare; it may arise from disease of the vertebra extending to the membranes, or from exposure to damp and cold, and from injuries. Moningitis, with an effusion of pas and fibrinous serum, has followed acute articular rheumatism.

Spinal meningitis, causing paralysis, has followed diphtheria, typhoid fever, small pox, and occasionally scarlet fever. An excellent paper has been written on this subject by Dr. Althaus.

"A had received a blow over the loins; an abscess formed which involved the vertebers, and the purulent matter entered the spinal canal, so that when he died, three weeks afterwards, the arachnoid cavity was filled with pas, and the inflammatory process had proceeded upwards to the brain, and there produced also an arachnitis." Spinal memingitis, in two cases of infants aged respectively three and four weeks, followed the injection of Morton's fluid by Mr. Callender, for the ours of spina bifida.

The symptoms are pain in the course of the spine, which may be limited to the cervical or dorsal region, and increased on movement; spasms of the muscles, eventual loss of motion, and paralysis. This latter is owing to compression of the cord by the efficient, and is often combined with bed-sores. Sometimes the disease extends apwards along the spinal canal, and produces inflammation of the cerebral membranes. The disease is not easy to distinguish from inflammation of the cord itself.

Pathology.—After death in these cases the dura-amehnoid is found thickened, the vessels are congested, and there is an effusion of serum and puriform lymph. When the pin-arachnoid is likewise involved (lepto-iscalegible) the cord has an irregular appearance, owing to the effusion of lymph within the arachnoid space. Where the inflammation arises from disease of the vertebra, and other neighboring structures, it appears localized in certains portions of the spine; but when, owing to a general cause, it may spread throughout the length of the spine, it selects always the posterior rather than the anterior surface. On outting the arachnoid lymph

is found beneath of a yellowish-green bas, toughish, or softer, or even puriform."

Treatment.—Leaching over the soat of pain and mischief in the spinal cord, a judicious and unstimulating diet, and the hypodenois injection of morphia to relieve pain, are the only measures to adopt.

Modifie, or inflammation of the spinal cord, is a very rare disease; it generally follows an bijury or pramia, or exposure to cold. Myelitis can be produced in rabbits by freezing the hind logs with other spray, and according to Dr. Althou, the first effect of the irritation is to cause spann and then puralysis of the Roodyssels by vaso-motor influence. The inflammation may attack the whole or a portion of the cord, and hence the symptoms vary according to the seat of the disease. There is pain in the back, and if the mischief is in the cervical region, difficulty of breathing. The disease may be attended with inflammation of the beain owing to the extension of inflammation from the cord, and the sympathy existing between the brain and splind system. With the advance of the disease, paralysis, sloughing of the skin, alkaline and albuminous urine, supervene. Death takes place sooner or later, and if life is prolonged, there is paralysis of motion and sensation in the parts below the seat of the discuss, It often terminates in softening of the cord, but never produces pus, except from pavemia.

An interesting case of acute softening of the spinal cord is recorded of a female child, 11 years of age, who was admitted into the Bristol General Hospital, with paraplegia, under the care of Dr. Clark, December 31st, 1873. The disease logan a week before admission with shivering and pains in her limbs, but she want about till three days previous to entering the hospital, when she suddenly lost the use of her legs. She never land convalsions, and there was no history of any injury to the back. There was pain along the vertebral column which was worse in the cervical region. It was not increased on pressure, and she could move her head about freely. There was complete paralysis of notion of the lower extremities. Sensation was diminished in the right lower extremity, and there was no sensation in the left. There was com-

^{*} Wilks and Morror, op cti., p. 24%.

⁴ Medical Society's Proceedings, vol. 1v, p. 76.

pleto loss of power over the bladder and rectum, uric acid, lithates, no allounes. Optic disks normal. The highest morning temperature was 99.4°; the highest evening 101°. The third day after admission there was partial paralysis of the upper extremities. On the fifth day there was more pain in the cervical region. On the sixth day, the urine was alkaline, ammoniatal, and contained pus and albumen. On the seventh day, the paralysis of the extremities had increased, difficult breathing and congestion of the lungs came on. On the tenth day, difficulty of locathing increased, and death took place.

Post services Emmonstion.—The verebral velus were congested and there were several points of injection in the brain, which was otherwise pule. "The spinal cord weighed ‡ ounce; the numbranes were healthy; there was a quantity of serous fluid in the analysis at ; the corrical portion of the cord was firm, but on making a transverse section there were several points of injection in it; longs congested; plouritic adhesions on the right side. The heart weighed 4½ ounces, and was healthy. Liver, spleen, and kidneys normal, but intensely congested. Stomach, intestines, uterus, and ovaries normal. The bladder was in a state of acute suppurative inflammation; the coat was very much thickened, and the nucous membrane lining the interior was covered with a yellowish-gray slough."

Treatness of Myelitis.—The subsutaneous injection of ergotias, as in the inflammatory stage of infantile paralysis, is recommended by Dr. Althaus, and when inflammation has subsided, helide of potassium to premote the absorption of any effused fluids and morfeld products. Later on, and-liver oil, phosphorus, friction, shampoolug, and electricity will be found serviceable.

An interesting case of dangated earlity in the spixed and (Springsmy feet is recorded by Dr. Frederick Taylor, of a female child, agod eighteen months, who was well till the age of five months, when it could not hold up its head, and from that time the head enlarged. On admission into the Evelina Hospital, November 19th, 1877, the arms became completely paralyzed. The head presented the characteristic signs of chronic hydrocephalus, and was very large. The anterior footanelles and anterior sutures were wilely open; the cychalls prominent, optic disks white, and vessels of the

Armis Softming of Spiral Cord, Lonors, vol. i, 1874, p. 442.

⁴ See Chap, XLVII, On Infantile Parallelle.

must size. Arms motionless and flaccid, legs distinctly rigid. The child got an attack of measles in November, and died of broschopneumonia on December 5th.

The post-unwrem revealed pleuritic effusion on both sides, and lobular payamonia at the base of the lungs. A post and a half of fluid was obtained by a trochar through the anterior fontanolle; the ventricles were greatly distended, and the fourth ventricle was large enough to contain a small walnut. "The membranes of the spinal cord were healthy. The cervical and lumbur regions had their usual consistence, but the dorsal region was quite faceid, and on making transverse sections it was som that in this region the cord was hollowed by a considerable cavity. The largest earity (for there were altogether three) was of irregular size and shape, and altogether extended from the lowest part of the cervical to the highest part of the lumbar region, and was two and a half inches in length." These cavities did not correspond with the central canal of the cord. Dr. Taylor quotes observations of other authors on this rare condition. This case is essentially, as far as efinical features show, an instance of hydrocophalus. No symptons that were observed can guide us to the suspicion of a similar state of the cord in other patients; neither must we forgit that in making post-mortem examinations of the brain, the cord is seldom examined, hence the presence of cavities may be more common than is surposed.

Corden spined Messingitis.—This formidable and fatal disease is of sufficient frequency and importance to be alluded to. Young persons are most liable to it, and children are not infrequently attacked. The disease has prevailed in the chief countries of the Continent, as well as in England, Ireland, and America.

It would seem to be sutitled to rank among the specific disenses, for it often occurs as an epidemic; it has a fatality like typhus, which it resembles; it is due to blood-poisoning, and not infrequently there is a petechial rash.

The covers appear to be due to cold and exposure, fatigue, bad living, and insunitary conditions, like typhus, but it is not contagions.

The symptoms begin with rigors, followed by fever, severe pain in the back of the bead, extending along the spine, and stiffness of the cervical muscles. Nausca and veniting are usually severe,

[&]quot; Pathological Transactions, vol. axis, p. 21.

In some cases described, the child falls into a state of stoper, means or cries, and then becomes unconscious, with a dusky countenance, from which state it does not recover. In other cases the intellect remains clear. The head is thrown backwards towards the spine, and there is tetanic stiffness of the muscles, paralysis, and oren convulsions. Disordered vision is not uncommon. The temperature runs up to 104°, or even higher in some cases; the pulse is quick and small; the tougue forred, the urine scanty, and semetimes albuminous. Petechial spots are seen over the face, neck, chest, and limbs, of variable size, and disappearing on pressure. Herpes on the lips is often noticed in connection with the disorder, particularly in mild cases. The disease may terminate fatally in a few hours, or it may last over a week.

"Spinal meningitis is by no recome rare in association with tubercular cerebral meningitis; and it is quite possible that some cases of so-culled 'cerebro-spinal fever' in children are really dependent upon tuberculosis, just as others may originate from traumatic causes."

From a number of cases admitted into the Dunder Infirmary, in December, 1877 and 1878, Dr. Machagan regards the discuss as contagious, and bearing a great resemblance to typhus. It sees in with rigors, intense headache, pains in the neck, limbs, and trunk. There is fever, and the respiration is quick and corsball in character; the patient is restless; the tongue dry and furred; urine high-colored, deficient in chlorides, and sometimes contains albumen. When an eraption is present on the skin it resembles the rath of typhus, but it appears earlier, and is lighter in color. The enticle desquamates freely after cerebro-spinal fever. The writer says it is distinguished from typhus by more sickness at the onset and more headache, the intellect is often clear throughout the illness, and there is a less tendency to delirium.) The resemblance, however, appears to me very close. The morbid appearances found after death were inflammation of the membranes of the nervous centres, lymph, and fluid effusion into the arachneid, and intense injection of the vensels of the pla mater. The veins in the spinal cavity were full, and there was vascularity of the membranes of the cord. One case terminated fatally in rupture of the spleen."t

^{*} Corebrospinst Mexicoginia editorial, the Lancet, 1976, vol. ii. p. 57.

[|] Contraspinst Ferry, the Lancet, vol. 5, 1878, p. 219.

^{\$} Table, 1978, p. 822.

In a case recorded by Dr. H. Vanslyke Carter, of Bombay, the patient was semiconscious from the first. On the third day he became insensible, and died on the fifth day. At the post-mortem examination the meninges were greatly congested, and over the convexity of the hemispheres was a layer of greenish-yellow pas; the spinal subamedanoid space was occupied with pariform lymph like that in the brain, and the effusion was almost limited to the posterior surface of the cord."

The favorable symptoms which precede recovery are a cessation of pain and fever, relaxation of the muscles of the neck, undisturbed sleep, and returning appoints.

The diagnosis is mainly grounded on the typhoid symptoms, the spidenic character of the disease, and the cerebral and spinal symptoms. The proposes is extremely unfavorable.

The model opportunities found after death are great congestion of the cerebral vessels, and effusion into the ventricles; congulated blood in the sinuses of the dura mater, and an explation of serum or pus among the meninges of the brain. Yery similar appearances are presented in the membranes of the spinal cord. "But when the case is as usual of mitigated, yet fatal, severity, you find it a pin-arachnitis, the lymph lying chiefly on the dorsal surface of the pin mater. Only in the very mrest cases do any products appear in the arachnoid space. The spinal cord itself in this discuss is often quite free from change." There are also sometimes evidences of congestion and inflammation in the lungs, plenra, and periamilium, enlargement of the sphere, falty degeneration of the layer and kidneys, and occasional unlargement of Peyer's patches.

Treatment.—Hitherto this has been most unsatisfactory, various methods having been tried, with small sucress. Leaches behind the ears, or capping along the spine may be demanded in some cases. Cold applications to the head and spine have also been found serviceable. At the onset, where there is high fover and delirium, the head may be shared, cold applied, and caloned given every four hours. The hypodermic injection of morphia to relieve

^{*} Note on the Occurrence of Cercles-sphal Mexingitis, Louces, vol. ii, 1878, p. 730.

pain, hydrate of chloral to procure sleep, and bromide of potassium to quiet the nervous system are severally indicated according to the peculiar circumstances of each case. If typhoid syngtoms are present, quintue should be reserted to, and as a rule, enemata, autritious food, and stimulants will be required.

Sexual proceedity or aberration is found in some children. The subject is a very disagreeable one, but its consideration cannot be eatirely omitted from a work of this kind. In boys the practice of masturbation may be caused by irritation produced by a long prepoce; in girls it is undoubtedly due in many cases to the irritation of ascarides, especially when they sucase at night from the anal ring and wander into the vaginal orifice. The little girl is thus induced to scratch berself, and so in time the habit is gradually formed. In both, the practice may be communicated by other children, who have acquired the vicious habit; at other times it is to be feared the practice is brought about by the improper conduct of nurses, and especially Indiau systs. When a child is fretful, the irritation of its genitals distracts it, and the excitement so produced is followed by languor and sleep. Occasionally, in girls, it results from vaginitis, as a result of dirty habits and general neglect. In such cases, earelessness on the part of the mother is much to blame. Where clouic spasms and paralysis are the consequence of this liabit in boys, to touch the meatus by a probe is usually followed by almost instantaneous erection of the penis, and by convuisive movements. The increasing development of the nervous system in both sexes, and the consequent tendeury to precocity, makes one fear that this evil practice is becoming more common. If such is the case, it is highly incumbent upon purents and guardians to recognize the fact, and to give assiduous attention to the warsle of their children and their associates.

Turks are four principal forms of paralysis in children:

1. Obstetrical paralysis.

2. Paralysis from brain discuse.

3. Infantile paralysis properly so called.

4. Duchenne's paralysis,

I. Gisterical paralysis sometimes occurs from pressure of one hinds of the forceps on the portio dura at its exit from the stylemastoid foramen. During the operation of turning, from undue violence the brachial plexus may be torn or injured, and paralysis of the upper extremity is produced. If any undue impairment of the cerebral circulation takes place, there may be hemorrhage of the corpus strintum, producing all the ordinary symptoms of cere-

bral benaplegia.

- 2. Physisysis from brain discuse may be the result of hydroxephalus, meningitis, apoplexy, and secrebral tumors. I once met with a case of hemiplogia, in a child nineteen months old, who had a subscute attack of meningitis and recovered. Paralysis is sometimes the result of rheumatism, typhoid fever, diphtheria, and especially scarlet fever. Disease of the petrons portion of the temporal bone may produce facial paralysis. Paralysis may occur during dentition, and be associated with convulsions and laryugismus stridulus.
- Tofactile, or infantile spinal purelysis, is a disease occurring in young children, the nature of which has not been satisfactorily investigated. It is particularly apt to attack children under two

years of age." It is a motor papalysis only, sensation being in no way affected. It is generally sudden in its accession, is attended with febrile symptoms, and ends in complete paralysis and waisting of the muscles. The limbs are not necessarily alone affected; the muscles of the back may be involved, and the spine more or less curved. It is generally the right lower extremity that is attacked. The brain and cramial nerves exhibit no morbid appearances.

Carres. The disease may appear suddenly in children who have not been previously out of health, or who have not suffered from any nervous or febrile disorder. Teething is not an uncommon cause. A child who came under my care with infantile paralysis in January, 1879, walked when he was a year old; he then partially lest the use of his left leg, whilst cutting a tooth. At two years old, when I first saw him, he could walk, but was lane, and the muscles of the affected limb were wasted. I have known the attacks follow cold and ulceration of the threat, dightheria, and the cruptive fevers. Blows and falls upon the hip have produced this form of paralysis. In rickety subjects, with delayed dontition, a child may suddenly lose the use of a limb, and wasting and contraction continue antil there is permanent deformity, such as ciuldoot, necessitating division of the semions. A child, two years of age, had beonchitis followed in six weeks by measles. A fortnight later paralysis of the lower limbs came on. He recovered quickly under the use of iron, strychnia, and shampooing. The disease may succeed convulsions in children, and irrecoverable paralysis may ensue. It crosps on insidiously in some cases, especially in excitable children who come of nervous parents. A little girl, aged seven years, under my care in February, 1878, with paralysis of the left arm, had lost two brothers-one of some cerebral disorder, and the other of convulsions, each at the age of one year.

Symptoms.—These often set in anddenly, the paralysis coming on in a few hours. A child may be playing about in his usual lealth, go to bed apparently in all respects well, and wake up next morning paralyzed in one limb or more; most frequently in the lower extremities, so that on attempting to stand or support himself he falls. The paralysis, or inability to stand, is the only symptom in many cases. There is no pain whatever. A male child, aged four

^{*} Clinical Lecture on Cases of Acute Atrophic Paralysis in Infants and Adults, by T. Barmed, M.D., rise Lancet, 1888, vol. 6, p. 925.

years, of pale and delicate appearance, came under my notice in September, 1875, with complete paraplogia. Two months before I eas him, he was playing on a lawn one evening in his usual health. Next morning he could not use his logs, and he was unable to do so for some months afterwards. The muscles of the calf became flabby and the joints relaxed; his appetite was excellent, and he had (as is most usually observed in these cases) perfect control over the sphinoters. The urine was healthy, the temperature normal, and there was no tenderness in any part of the spine. He was ordered friction with bay salt for the limbs, flancel clothing next the skin, and the syrup of the hypophosphite of iron twice daily, as he was weak and pale. A fortnight later there was some improvement, for when his feet were allowed to touch the ground he could move one foot in advance of the other. He elso crawled about the floor with greater ease than at first, and and not allow his legs to remain so long at rest. A month afterwards he moved his legs with still more freedom when supported, with his feet touching the ground, and he had more confidence in himself. The muscles of the calf in both legs were much less firm than those of the nates and thigh, which were in no degree wasted; the loins were well developed, and the patient sat up fairly wall in a chair. The spine was nowhere prominent, nor was inv tendemoss felt on percussion. He could move the left legwith the greatest case when sitting down, pulling it up rapidly under him, but he could do nothing with the right leg in the way of lifting it up like the other, though he felt the ground with it, and when the sole was touched with a pin, or tickled, he complained, but not the least reflex action was induced. The right foot was colder and more swotlen than the left. Iron and strychnia were prescribed.

In 1878 the child could walk when taking any person's hand, but the muscles were still wasted and weak, and he moved along timidly and insecurely. There was a tendency to distribute.

In some cases there is febrile disturbance, which may last several days, with thirst, loss of appetite, benduche, acreaming, convulatous, and loss of consciousness. These symptoms may rapidly develop themselves after the paralysis has been ustablished. In other cases again there would appear to be no fever.

The arms may be alone affected, but more commonly the legs, tometimes one arm or one leg, or one arm and leg of the same side,

or opposite sides. In very exceptional cases both arms and both legs are affected, but, as previously stated, the right leg is the most frequent sent of infantile paralysis. When the paralysis occurs in one arm, say the left, the patient will use the right hand to eat or drink, and make no use of the left whatever. The thumb and fingers may be widely separate, and the back of the hand when extended has a rather concare appearance. The hand drops at the wrist as if useless, the thumb is flexed inwards towards the palm, and the phelongeal articulations are all loose. On attempting to take up anything the child will slide the object to the edge of the table before it can be grasped. The hand will swell when cold and look binish. If the leg of the same side is also affected, so as to constitute Lemiplegia, or indeed if it he alone affected, the child, eren with assistance, walks unsteadily, the limb being moved with less freedom than the sound one. He turns out his foot, the ankle-joint being bent inwards at the same time, so that he rests chiefly on the inner horder of the foot. On looking upwards the patient is afraid to venture to walk; he requires to watch his foot at every step.

Considerable wasting in the muscles of the glutcal region and thigh may often be observed. In some cases it is chiefly noticesble in the gastroonemins, and the muscles of the foot, especially the small interessed. The affected limb, from diminished size of the bloodyessels, generally feels much colder than its fellow, and is damp; the toes too present a bluish aspect, and there is a linbility to chilldains (Buzzard, op. cit.). The paralysis is attended with flaccid mancles, and signs of atrophy; the muscular tions undergoes degeneration or absorption, so that in severe cases it almost outirely disappears, and leaves the skin in close contact with the bone. The ligaments are relaxed, and deformity of one or both feet is not uncommon. The patella tendon reflex is absent in the affected limb. The extensors in infantile paralysis are more frequently affected than the flexors, and as a result of this the flexors become permanently contracted. Redex excitability is soon abolished, and the muscles do not contract under the outdorment of faradization. "Many of the muscles paralyzed loss their faradaic excitability entirely within a week, and rapidly waste-But although they fail to respond to the strongest induced currents they react to slow interruptions of the constant current preaction of degeneration). The nerves to the museles, on the other

hand, lose their excitability to both forms of electrical excitation. Some, again, of the muscles whose faradaic excitability has been lowered, but not lost, are not long in regaining the power of contraction to voluntary impulses."— In mild cases, the use of the battery maintains the contractility of the muscular fibre till the fendamental cause of the disease is remolied, thus preventing permuonal and irremediable nunscular strophy. In this disease there is an absonce of pain, and a freedom from irritation of the skin, and bulsores, a fact which distinguishes it strongly from other forms of paralysis.

The urine often contains excess of phosphates. These were

present in two cases under my care at the same time.

A remarkable case is recorded by Dr. Andrew and Dr. Dyce Duckworth, shows that a form of "all but universal paralysis" may occur in childhood from exposure to beat, and be followed by complete recovery. The patient was a little girl two and a half years old. There was almost complete loss of motor power in her arms and legs, and anasticia of the affected parts. The muscles were soft, wasted and flabby, and the urine and forces passed involuntarily. The authors considered that the cust differed from essential infantile paralysis in the affection of the sphinoters, and the disturbance of sensation. They were of opinion that the symptoms were due to profound nervous exhaustion, affecting the spinal marrow as well as the muscles. Steel, colliver oil, and belladonna were prescribed. Faradization was practiced stally. The child recovered in two months.

Pathology.—The disease is attributed by recent observers to inflammation of the anterior cornus of the gray motor of the spinal cord, whence the motor roots of the spinal nerves spring. The large rolls become atrophied and at length disappear. According to Charcot, the disease begins in an inflammation of the gaughoric cells of the anterior cornus of the gray matter of the spinal cord, which gradually spreads to other parts. The recovery of the limb depends upon the recovery of these cells. It may affect any portion of the cord, cervical, lumber or dorsal, but the latter is the most rarely involved. Alluding to the morbid changes by Bristowe says "the diseased cornus ultimately shrink in proportion to the degree and duration of the morbid process."

Burnel, ep. cit., p. 925.
 Med-Chit. Tens., 1977, p. 253.

I Principles and Practice of Medicine, 1977, p. vol.

The muscles do not shrink in all cases. "Occasionally they present a positive increased bulk, owing to the accumulation between their fibres of adipose or fibrous tissue." Dr. Althous writes: "Infinitile paralysis is an extremely acute myelitis of suoderate intensity which is either diffuse, or occurs in circumscribed areas, and affects more particularly the cervical and lumilar enlargements of the sord." In cases that terminate fatally after a lapse of years, the anterior corans are found wasted and the cells disintegrated, whilst the posterior corans are lealthy. The suppoles are soft and atrophied, more or less replaced by fat, and the interstitial tissue hypertrophied; the tendous are smaller, the bones shorter, and the medullary canal is enlarged;"

^{*} Principles and Practice of Medicine, 1877, p. 201.

⁺ On Estimile Paralysis, 1878, p. 15.

¹ Some interesting microscopical speciment of the spinal cond were exhibited before the Phthological Society (February &ch. 1879). The spinal outd is the few uses use from a child, three years aid, who had seffered from infantile paralysis days the age of fillers months. There was a history of a blow on the hip, followed in three days by pain in the left leg, paralysis, and forerishness. Pain lasted sen days, and then paralism remained. The child died of branchequenteerin. The musics of the left leg were pale in online and not and printingua in consistence. The huntur parties of the cond was disconsisted by size on the left side, and the interior costs of the lumber serves were smaller. Microscopically there was almost complete almence of news googiest orde in the left sateries owns; the salestance forming the business the goay matter had bet its open spency termine, and presented a uniform feltile appearance. In the asset case a child, two and a half years old, had a fall which did not agrees to harrie; thirteen days afterwards the bit arm and leg became paralyzed. Then both legs last mixtion and sensation, both arms were powerless, but had not lost amention. The committee were irrelaterry. The child took mender, and died of lecodepartners in time weaks after the acciding. The spital cord was practicities and, and the grey rester was thick, and there were putriso of red softming in the primite corpus in the landar regions. Above the softened parts there were a large marker of lencogytes in the peritocular spaces. There were no gaugien cells on the left side, extelation corporder, granular lealies, and free under took their place. The proprint heren were discount, but paste on the right side than the left. The charges with west marked in the certiful postion of the cond, then in the fusher and her in the derest; there was distinct scheening in the statem lateral columns of the cord, especially on the left side. In the clied case the child, aged those and a half years, died of murlet fever. At seventeen months old the fell fill with "relaxed howin," and maumbie to walk, which the find proviously done. The power of walking soon sourced tica limited extent. Weakness was especially uniroutly in the left leg. The lamber region of the spinal nord was found on section to be smaller on the left than on the right aldo, and it was most murked in the interior corner; the posterior corne were equal has size on the two sides. On the left side the graption calls of the arieries come had murrly disrepented; there was no sclerosis of the asterior hours or of the antero-lateral columns.

Treatment.—The fact that several distinguished authorities speak of very different remedies is conclusive that no specific has yet been discovered; which is not to be wondered at considering the obscure origin of the disease. In the early stages, where there are febrile symptoms, saline aperients and medicines which control fever are necessary. Two or three leeches to the spine, and counter-irritation are serviceable. Nothing can be done without the most absolute rest. When febrile symptoms have departed, we must endeavor to restore the power of the purelyzed muscles.

One of the most recent writers on the subject (Dr. Althaus) holding the theory that the disease commences in inflamnation of the anterior cornua, strongly recommends the subcutaneous lojection of ergotin. He proceeds on the principle that this alkaloid matracts the minute bloodyessels of the spinal cord, and controls the hyperconia. "I used a solution of Bonjean's ergotin in distilled water, which, if thoroughly pure, is generally not irritating; and the dose I inject is one-fourth of a grain for a child from one or two years of age; one third of a grain from three to five years; half a grain for children from five to ten years of age; and a grain for patients upwards of ten years. These injectious must be repeated according to the symptoms which may be present, either daily or twice a day. Our guide of netion in the matter should be the thermometer and the pupil. In severe cases, where the thermometer runs up to 1037 or 1047, the remody should be used more freely than when the thermometer shows only a rise of one or two degrees. The fever being in all these cases a secondary phenomenon, consequent upon local inflammation, may be rapidly reduced by the use of the ergotin, which thus proves a truly antiphlogistic remedy; and its employment should be continued antil the temperature has fallen to the normal standard. Where the pupil remains much contracted after the use of the remedy, some time may be allowed to classe before it is again injected, but where it is large, the dose may safely be increased and repeated. The injection is not painful if well performed, and is quite as easily done, even in restless children, as it is to make them swallow a dose of medicine. The place of injection is a matter of indifference, I generally inject into the logs, as most convenient."

I have had no experience of the subcutaneous injection of expension, recommended by Mr. Barwell.

^{*} On Infantile Paralysis, 1818, p. 50,

Belindonna is useful by controlling a hypersmic condition of the cord, and its mombranes. "In consequence of this influence, it diminishes the amount of blood in the vertebral canal, and in so doing produces a relative diminution of the vital properties of the spinal cord and its nerves." Ergot of rye has a similar action.

When the incipient or inflammatory condition is reduced, small does of indide of potassium in combination with bark are serviceable, and the remedy should have a fair trial. It checks inflammatory offusion, and lessens the growth of connective tissue.

Where the disease is advanced it is generally admitted that no benefit can be afforded except by galvanism and fundization. A continuous current, from ten to twenty rells of a Stohrer's lattery, to the spine or extremities, sometimes causes no muscular response, and the outaneous screibility may be diminished. This treatment, however, will often have a weedlerful effect in restoring the true of the muscles and nerves. In those cases in which redness of the skin is excited, and the feeling of pins and needles is produced, recovery may be generally anticipated. The stillty of the faradiration lies in its maintaining the functional activity, and with it the putrition of the muscles, until the nervous disease is recovered from. When it is employed early, before degeneration or utrophy has reached any important stage, the disease may be arrested, and the deformity removed. It is a good sign when the paralyzed muscles contract and become warm under the influence of faradization, and the child shows indications of pain by drawing up the log or arm as the case may be. A child may my from the first two or three applications, but he mon gets accustomed to the paenliar sensation. The operation should be continued for ton minutes daily.

After this form of paralysis has lasted some time and the musslex have recovered their tone and strongth, the patient may be mable to exercise the will, so so to bring the hand, or the legs, properly into use. This complication must be overcome by careful drilling. "When any amount of voluntary power has been restored by electricity, it is most important that the child should be encouraged to use the limb, and practice various movements."

Pundysis of the Lower Extremition by E. Bersen Sequend, M.D., F.R.S., 1965,
 111.

A Handbook of Medical and Surgical Electricity, by Herber Tibbin, M.D., 1977,
 p. 101c

Infantile paralysis is a very chronic and tedious disorder, and in some instances the treatment has to be persevered with for months or even years. Muscles which seem almost hopelessly wasted and paralyzed, sometimes completely recover their size and form under a steady continuance of local and constitutional measures.

The use of Iron, strychnia, and col-liver oil, where there is general arcemia, and an absence of congestion and spinal irritation, ought to be steadily continued for weeks or months together. It is an excellent plan to immerse the affected limb in hot water for ten or affect minutes daily, before shampsoing is commenced, and both night and day, to maintain the warmth of the affected muscles by a stocking of "pure span silk" or "channels leather," as recommended by Dr. Tibbits. Cold affusion and friction of the limbs are useful in restoring the tone of the wasted muscles. Mountain air, or a senside residence, is advisable in some cases.

The deformities that result from infantile paralysis will require surgical treatment.

Declarac's Parelysis (pseudo-typertraphic overalar paralysis).—
This disease is now well known to the student of medical literature, from the researches of the late Dr. Duchenne, of Boulogue, whose name is, at least at the present time, always associated with it. Since that physician and later observers turned the attention of the profession to the complaint, it has been found to be less rare than was at first supposed. Butlin had the opportunity of making observations on four cases, all under treatment within the same year at the Children's Hospital, Ormond Street. The disease is most frequent among boys. Of twenty-three cases mentioned by Dr. Gowers, eighteen occurred in boys.

It is a rure form of paralysis accompanied by enlargement or hypertrophy of certain muscles. It may occur in children who are born healthy and vigorous, and who have passed through the period of dentition well. The majority of cases begin about the sixth year, and death occurs between 14 and 18. The rich are more prone to suffer than the poor. It would also seem to conson after any severe illness, as measles. The disease is slow and shrould, and unattended by fever. No definite cause has everbeen assigned, but authorities generally agree that it is most frequent in dull and idiotic children. Six cases are mentioned as having occurred in the same family, and in another instance eight brothers died of the disease."

Symptoms. - These are, first those of weakness in the lower limbs, and finally loss of reflex excitability. If the child is old enough to walk, he moves along with a shuffling gait, placing his feet timidly and cautiously on the ground. He aways his body from side to side, and swings his arms at every step he takes. The belly is prominent or arched forward, the shoulders are thrown back, and there is a curve along the spine (lordosis). He is apt to tumble down if he meets with any impediment in his way, and cannot get up again without assistance. He stands with his foot apart to balance himself, with the toes averted. In attempting to rise from the ground, the movements are very possing; the patient bends one knee, first placing his hands on it or some object most by for support, he then hends the other knes into the kneeling position, and so grasping his thighs from below upwards, gradually raises his shoulders and body to an apright position, proceeding in a very cautious and gradual manner, as if in fear of falling. This peculiar action has been considered pathognomorie. "Attention was called to it by Dachenne, and I have never seen it absent in a case so long as the patient possessed the necessary muscular power. I have never soon it in any other disease, and every doubtful case in which it was present ultimately proved to be no example of the affection. Its diagnostic importance is thus very great."+

The disease first shows itself by the child being quite unable to walk when old enough to begin to do so, or if it has reached the age at which it can stand by itself, or walk, or run, it becomes very weak on its legs. This weakness continues for many months, progressing slowly, when the careful medical attendant, on examining the patient stripped, will at once secognize the disease if he finds that, after months of muscular weakness, the muscles of the leg have become larger and not smaller. In a few more months the hypertrophy extends to the buttocks, or even to the loins, the weakness increasing rapidly. The great firmness of the affected muscles when set into action would puzzle the uninitiated as it resembles what is seen in muscles hypertrophical by healthy exercise.

^{*} Pseudo-hypermophic Paralysis, by W. R. Gowers, M.D., 1973, p. 8.

[†] Pseudo-Lypertrophic Muscular Paralysis, by W. H. Gusses, M.D., 1879, p. 4.

This hypertrophic stage lasts several years, and is followed by gradual and complete paralysis; the unaffected another hote motor power; those involved in the characteristic enlargement all diminish in size. The patient, now perhaps grown out of childhood, ultimately dies through falling a prey to some visceral affection, as is the case with most patients attacked by the other rarer and slower forms of paralysis.

Pinhology.—In this peculiar form of paralysis, the muscles of the calf of the leg become enlarged and overgrown, and present a remarkable contrast to the muscles of the thigh and other parts of the body. In one case the gastrocuemil were abnormally firm when at rost, and during contraction, hard and knotted as the biceps of a blacksmith.* Dr. Gowers found that on catting into the gastrocuemius in one instance, it presented the appearance of a fatty tumor. It was a mass of greasy fat without any muscular reduces.† The microscope reveals a degeneration of the numeriar fibres, both in size and number, and a great overgrowth of the remarkive tissue between the bundles of fibres; fat is also deposited freely over the affected part of the numeric, but the fibrous hyperplasis is the primary morbid change.

In one case related by Dr. Crd, there was increased temperature in the affected Segs, compared with the thighs, of from 1.8° to 88°.2 In another case, also described by him, the thighs were surmer than the calves \$

Proposits.—This is extremely grave. The patient may possibly recover if the disease should become stationary, but it generally extends upwards, and the functions of deglutition and respiration becoming involved, death takes place from exhaustion or asphyxia. The fital result is not due to the disease itself, but, according to Dr. Gowers, to some intercurrent malady. "The weakness and wasting of the thoracic muscles, for instance, gradually lessen the respiratory power. The patient is thereby weakened, and is rendered in easy prey for the maladies which lie in wait for the infirm. The most common cause of death, indeed, is the direct interference with the action of the lauge. As the patient becomes weaker, bronchial cities are heard through the chest, dyspaces comes on, and is rather increased than lessened by the patient's feeble at-

^{*} Med-Chie, Trans. 1877, p. 21, Pseudo-hypertrophic Paralysis, by W. M. Ord, M.D.

tempts to rough. Pyroxia may be developed, and the patient dies with the signs of a chronic bronchopacumoula, which has in many cases been found after death."

Treatment.—This is in the highest degree unsatisfactory, and must be chiefly symptomatic or pullintive during the later stages. When the disease has lasted only a short time, it may sometimes be returbed or arrested by friction, galvanism, and unscalar exercises. Amenic and phosphorus are among the best remedial agents; coldiver oil is preferable to either.

Neurolyja is rare in children, but the practitioner should be aware of its occasional occurrence. I have met with a few cases of facial neuralgia in young children, apparently independent of gastric disturbance. One, a most severe case, in a girl nine years of age, which yielded to good food and quinine. I am assured by the mether that her child, four years of age, suffered from paroxysms of severe pain in the right leg and heel, which medical men thought was neuralgic. Gennine neuralgic, or one-sided headache temperarchital neuralgia) is equally rare in children; but it is recusionally met with in anomic subjects if badly fed or overworked at school. Neuralgia sometimes attacks the intercestal nerves, producing pleurodynia, or the brachial plexus, ransing brachial neuralgia. Attacks of pain over the cardiac region in delicate children are often of neuralgic origin.

Acure rheumatism is a most painful disease which attacks the larger and smaller joints, but especially the former; it is accompanied with fever, and is prose to involve the fibro-serous struc-

Gorero, ep. ck., p. 40. † Heudacher, by W. H. Doy, M.D., 3d edit., p. 366.

tures of the heart and pericardium. Rhomantism is not so frequent in childhood as in youth and adult life." The youngest child I have seen with rhomantic fever was nearly six years old. Vogel has met with a case in a child one year and nine months old, who succumbed to disease of the heart after three months. It closely resembles the acute rhomantism of adults, but it is usually less sessere and protracted. It is essentially a disease of the joints and of the heart, the structure of its lining membranes being, as Mr. Hilton points cut, like that of a joint,—fibro scrous.

Symptoms.-These begin not unlike a common cold, with pain in the back and limbs, followed by shivering and feverishness. After the lapse of a day or two, or it may be a work, one or more of the larger joints become swollen and painful, the surface is hot and inflamed, and the tenderness so great that the least movement of the bed will aggravate the suffering. The pain in some cases is most erratic, it may begin in the side, and the next day attack the knees, ankles, aboulders, or fingers; one day it may be confined to the feet or knees, and the next day it may seize nearly all the joints, lingering for an uncertain time in one or more; and the child suffers from rostlessness and sluplessness, or delirium at night. It should be borne in mind that delirium in the course of electratic fever is usually the consequence of exhaustion, and if the pulse is at all unsteady, and the skin freely sresating, stimulants may be seeded. There is loss of appetite and thirst; the neck is so stiff in some cases from implication of the cervical muscles, that the child cannot bear the head elevated to swallow fool, the slightest movement increasing the torture. Even inspiration is painful if the pectoral muscles are implicated.

The temperature varies from 101° to 103°, or more, and there are few diseases in which it may run so high. Dr. H. Weber has recorded an interesting case where the temperature reached 103.2°, with delirium, and other brain symptoms, in a lad 16 years of age. The patient recovered under cold baths and cold affusion.

The pulse is full and soft; at times hard and bounding, from 100 to 120; the tongue is coated with a thick white fur, the boxels

^{* &}quot;Of the ages of patients affected with scate ricementing, out of 100 cases adwited into the London Hospital, two were between 0-10, minutesian between 10-10, strong-screen intercens 10-23, derly-three between 20-25, twolve between 35-41, and its letween 40-55."—Expert of the Moderal Equation for 1976, by G. ¹ Diseases of Children, 1874, p. 232.

are costive, and the skin is bathed in perspiration of a sour and sickly smelling character, which brings no relief to the pain and suffering. Everything about the body of the patient is acid, the saliva is acid, the sweat from all parts of the body is acid, and even the breath has an acid odor. The urine is high-colored, intensely acid, and scanty. On standing in a deep ressel for a short time it throws down a copious pink deposit of arate of ammonia. The chlorides are deficient. It is occasionally albuminous both in adults and children. This arises from congestion and renal irritation, due to the rienmatic poison, or perhaps the high temperature; just in the same way as it often occurs in some other acute diseases marked by pyrexia, as scarlatina, meades, and bronchitis. It must not be inferred in such cases that the kidneys are really unsound. The high specific gravity is a proof of temporary congestion, caused by the increased work thrown upon the kidneys.

As regards the pathology of the disease, it appears to depend on an excess of factic acid in the blood. Dr. Bulthscar Foster has recorded several cases where the symptoms of acute rhounatism were produced by factic acid, given for the treatment of disheres.* If blood be drawn from a vein it is found to be both buffed and supped, the fibrin being in excess.

The date when improvement commences is uncertain. It may commoner in a few days after the disease has begun, and the duration of it is certainly shorter than it is in adults, but it may be delayed longer, and last from a month to six weeks. The symptoms that indicate the decline of the disorder are an abatement of the pain, calm sleep at night, and a free and copious discharge of urine, which throws down a deposit of lithates.

Relapses are common; a little boy, aged eight years, was admitted on five separate occasions into the Samaritan Hospital with acute articular rheumatism, and an aggravation of mitral mischief consequent on the first attack.

In many cases the heart becomes involved during the progress of the articular inflammation, and the younger the patient the more likely is this to occur. The symptoms which indicate this serious complication are not always obvious. The cardiac affection map steal on imperceptibly, and be overlooked till the joint affection subsides, and there is an abstement of the pain. A mederate degree of febrile disturbance, and a slight affection of the joints, afford no guarantee that the heart will not become implicated in the course of the rheumatic affection; indeed, it may be the first organ seized upon in these young subjects, before there is any pain or swelling in the joints. So much is this the case, that the heart affection may be the first symptom to raise suspicion of the nature of the malady, and it is, therefore, wise in all cases of obscure febrile attacks in young children, to amendate the heart carefully and frequently lest the disease be overlooked. But, as a rais, if endocarditis or pericarditis is about to happen, there will be restlessness, or even convulsions, dyspace, pain in the cardiac region, opprossion, and inability to be on the left side.⁸ In other cases, bronchitis, premnonia, or plenriey superrose, and even inflammation of the brain.

Crease.—The disease generally follows exposure to cold and wet in delicate constitutions, repecially if there is insufficient clothing. A previous attack renders a child susceptible to a return. The rheumatic diathesis, too, is very marked to some families. "Of twelve children of a mother who had suffered from sente rheumatism and heart complication, eleven had the disease before they were 30 years of age.). This is probably as remarkable a record as could be found in the history of the disease. Acute rheumatism sometimes follows scarlating.

Proposits and Consequences.—If the disease is confined to the joints, and the urine throws down a copions lateritions sediment, with an abundance of uric acid, the case is favorable; but if the articular inflammation suddenly becomes less, and inflammation is lighted up in the heart or brain, then the prognosis is less favorable. The disease rarely terminates fatally, if ancomplicated, but is apt to lead to valvular disease of the heart (especially mitral mischief), to be followed by a chronic form of the complaint. As reliques are very common in rheumatic fever, the treatment should not be abundaned too soon. Injudicious feeding, and especially teerindulgence in animal food, frequently invite a return. The younger the patient the greater the liability to heart affection.

Transcat.—The most absolute rest should be maintained, for any movement not only amounts to torture, but relapse is less likely to ensue when patients are kept long enough in bed, and on

^{*} See Perionditis in Chap. XLI, p. 532, On Discuss of the Heart.

⁵ Steiner's Diseases of Children, by Lorson Tait, 1874, p. 334.

a liquid diet. "Extreme repose is worth all the other means of relief put together." So that she earlier the child suffering from the disease comes under treatment the shorter is the probable duration of the complaint. The sheets to be removed, and the patient clothed in flamed, whilst the diet should be a fluid one, consisting of milk, light broths, and arrowroot.

The chief object at the toginning of treatment, is to encourage a free action of the skin and kidneys, to unload the bowels by a freely acting purge, in order to drain the nincous membrane effectunlin. For this purpose a dose of calomel, followed by an aperient mixture (Form. 8-41), or compound jalap powder, or compound lignorice powder (Ger.), will be necessary. So long as there is high ethenic action, the bowels must be kept open; yet, active parging accessarily bayelves movement. The necessity for purging is often very obvious, whilst its disadvantages are equally as, and therefore it becomes a difficult question in practice to decide whether the patient should be purged or not. If there are pink lithates in the urine, a copious supply of potash is needed. If there is severe pain, opium, or some preparation of it, as Dover's powder, ought to be given freely to relieve it; either alone, or with alkalies in large doses. For the relief of thirst, burley-water flavored with lemon, seltger-water, toust and water, or pinin water are indicated.

There is much to recommend the view that, when the urine is alkaline, the heart is generally safe. The late Dr. Fuller said, "In no single instance has a patient of mine been attacked with subcarditie or pericarditie after the urine has shown an alkaline reaction."; This may be effected in the space of twenty four hours, if large doses are given at intervals of three hours during that

time. Alkalies appear to possess the power of keeping the fibrin in a soluble condition, and so preventing its deposition on the valves of the heart, whilst they tend at the same time to parify the blood by increasing the action of the kidners. According to Dr. Richardson, carbonate of ammonia possesses this power of maintalning a fluid condition of the blood in a greater degree, and although it has not the same infrance over the rhenmatic affection as potash, it may sometimes be combined with it advantageously when there is depression." Antimony acts in a similar manuer, and likewise controls the force of the circulation. "Still, there are a certain number of instances where true rheumatic inflam mation is very obstinate, and does not yield to the alkaline method. And in these you will find the periosteum and perichondrism affected. When, then, after five or six days the patient is no better, er but little better, I add ioslide of potassium to the potash, and in a few days more continue it alone during the convalescence. And, of course, if I am enabled to make out this condition of pericotenns at the first visit, I begin such treatment straightway."

During the last few years the introduction of salicin and its compounds into practice has found some warm advocates. These preparations possess the power of reducing the high temperature of scale rhoumatism, and the pyrexia of some other discusses, Salicin, salicylic acid, and salicylate of soda, have a very decided effect in shortening the duration of the pain and fever, and in reducing the percentage of heart discuse; but of all the three remedies employed, the last is perhaps the best.;

Saliein was first introduced by Dr. Macingan, of Dundee. He recommends that it be given in large doses, twenty to thirty grains every two hours for an adult till the pain abates. Of course smaller doses will be required for children. "We are imbelted to

^{**}When fibrin is as yet in solution in the blood, it is the easiest matter in the world to keep it third; the soldition of a very small quantity of allials, say two parts of alkalities a theorems of blood, is sufficient for this purpose. But, when their law or pursued, in resolution in a difficult matter." — On Fibrinana Deposition in the Heart 1952, p. 40.

^{*} On the Treatment of Acade Rheemanism, by T. K. Chambers, M.D., The Lancet, vol. 5, p. 200, 1882.

[†] Of 80 cases of sente chemistism, recated by salicin and its compounds in the Lember Hospital, in 1876, the average stay in the Rospital was 16.1 days, and those tented otherwise 41.9 days. The symptoms slidded somes under the first mode of treatment; the direction of the pain and pyroxist was shorter, and there was a less lisbility to hand discuss. Bolapses, however, were rather more common.

C. W. Brown, late House Physician at the Boston City Hospital, for the most valuable and extensive investigation into the action of salicylic acid on rhoumatic fever. He records 160 cases, taken indifferently, the patients being of each sex, and of all ages between 18 and 61. The drug gave considerable relief from pain on an average in 1.46 days, and complete relief in 2.8 days. The average time of treatment was 6 days, and the average number of days in hospital was 18 days."

All authorities agree that salicylic acid has a remarkable effect in reducing the temperature of rheumatic fever. This it does affeetually and rapidly, but relapses, as vomiting, vertigo, profuse sweating, and collapse do sometimes arrend its employment, and, therefore, it is well to be prepared for these symptoms. Dr. Whipham, of St. George's Hospital, and Mr. Poole Collyns, resident Medical officer at the Atkinson Morley Hospital, Wimbledon, treated at the latter institution twelve cases of acute rheumatism with salicin, salicylic acid, and its salts, with a view of arresting the disease at its caset. In some of the cases the disease visided after a few doses, and in others the pains were relieved in a few days. In two of the cases, attended by a pericardial frictionsound, the symptoms passed away in four days after commencing the treatment ! Dr. Greenhow considers that saliein and saliey. late of soda do not prevent complications arising in the course of rheumatic fover, which are equally frequent during this treatment; the patient is peither better nor worse, nor is he disabled for a longer or shorter time after it. Amemia appears to follow the salleylate of soda treatment, and health and strength are slowly regained. The pain and distress of the patients are lessensil by both these agents, but the duration of the illness is not shortened. Dr. Greenhow expresses his conviction that the weakening of the first sound of the heart indicates an influence upon the muscular structure of that organ. He prefers blisters in the vicinity of the painful joints as affording speedy relief, and not producing so much subsequent debility.

In the relection of saliein, salicylic acid, and its salts, some difference of opinion prevails amongst medical men, as to which is the

test of these remedies. Salicin is more soluble than salicylic acid, it is less likely to cause sickness, and is not so unpleasant to the palate; it may be given with a little syrap and aromatic water." Salicy lie acid may be combined with the liquor ammonie neetatis, ? or the blearhouste of potash. Salieviate of soda may be given in plain water, with a little simple syrup ? It is now generally admitted that the last is the best form of administration, owing to its solubility and the rapid manner in which it is absorbed. Respecting the use of salicylate of soda, Dr. Cavafy says: "With regard to dose and mode of administration, I am convinced that the best plan is to thoroughly saturate the patient with the remedy at the commencement, and then to gradually diminish the dose and lengthen the interval after a distinct result has been produted. Relapses are best avoided by continuing the drug in small doses during convalescence, in just sufficient quantity to cause the urine to give a violet tint with perchloride of iron," Dr. S. J. Simrkey says "that the presence of albamen in the urine does not contraindicate the exhibition of salierlate of soda," and Dr. Theodore Ackland "observes that of five cases of acute rheu-

matism with albuminuria, the albumen disappeared in each case while the drug was being administered." Nerrous symptoms, in the form of bendache, deafness, singing in the cars, and occasional delirium, as well as nauses and veniting, have been observed to follow the use of these remedies. It is also worthy of especial notice that their exhibition does not prevent the occurrence of heart complication, and that the liability to relapse is considerable.

When pericarditis supervenes in the course of rhoumatism, and zente pain is referred to the cardiac region, no time should be lost in applying three or four lecohes, if the patient has a hard pulse, and is strong enough to bear depletion. Heaviness of manner, heat of skin, and any degree of pulmonary congestion, with a dry cough and quick breathing, are among the indications for their employment. Moreover, the pain in the chest alone sufficiently justifies the practice, for its continuance further excites the action of the heart, and aggravates the serous inflammation already begun, by accelerating the circulation, and permitting that extra motion to the walls and valves of the heart which, in the progress of pericarditis or endocarditis, are so much in used of rest. Generally, I believe, a mustard poultice, or repeated linseed positioes, will supply the place of leeches; still they are useful in the cases I have pointed out. Opiom, or hydrate of chloral, must be resorted to whilst pain and sleeplessness are leading symptoms. Opium, especially, soothes the nervous system, controls the burried circulation, and reduces the frequency of the pulse.

In cases where the temperature suddenly rises very high, and death threatens from delirium and exhaustion, no remedy is so likely to save life as the cold bath. It has been employed, with the best results, by Dr. Wilson Fox, and some others in cases of hyperpyrexia in neute rhemmatism, when the thermometer registered 197°, 108°, 109°, and in one instance, recovery took place after the temperature had reached 110°.

These cases were complicated with endocarditis, pericarditis, rigidity of the muscles, defirium, and coma. Dr. Fox put his patient with a temperature of 110°, into a both of 95°, and reduced it gradually by adding lumps of ice, and pouring iced water over the patient rapidly. The average temperature of the

^{*} St. Thomas's Hosp. Heparts, p. 402.

both was 65°. In this remarkable case, the patient, a female aged 49, took each day for two days, eighteen comes of brandy in the twenty-four hours, sixteen comes of beef tea, four pints of milk, and seven eggs." It seems that we possess a remedial agent in the cold bath of extreme value, when venescotion, salicin, and large doses of quinine, have signally failed. When a child has this very high temperature, and life is despaired of through the failure of other remedies, I should unbestratingly have recourse to it.

Local applications are of great value in relieving pain. The affected joints should be awarbed in cotton-wool, and then covered with col silk, a plan which conduces to the repose of the parts and to the comfort of the patient. A piece of lines rag saturated in a solution of bicarbonate of potash and landanum may be had recourse to if the pain is severe and the joint hot. The solution must be warm, and cotton wool afterwards applied to the joint.

The plan of blistering the joints, as recommended by Dr. Herbert Davies, is an excellent one, and, speaking from my own experience, I should say that nothing relieves the pain more effectually than the application of strong blistering fluid to the affected part. After the application, the joint should be protected with cottonweel as just described. The discomfort caused by the blistering soon passes off.

As soon as the more acute symptoms begin to subside, bark should be given, and if the urine is still high-colored, potash should be added to it.† When the alkaline treatment is changed for the tonic, the ammonio-citrate of iron with the bicarbonate of potash is very useful,; and later on the syrup of the lodide of iron may

be substituted with advantage. Cod-liver oil, too, is a valuable remedy to children of a strumous diathesis.

Too much care essent be exercised in restricting the use of animal food, for fear of increasing the lactic acid in the blood, and either fostering the disorder, or bringing on a relapse, as I have already noticed; hence the propriety of giving suitable food sparingly, and of a non-sitrogenous character. Dr. James Andrew has written an interesting paper on the subject.* An abundance of milk, together with vegetable and farinaceous food, such as greel, arrowroot, rice, and tapican pudding, are the safest kinds of nonrishment till every relie of the disorder has disappeared. When the complaint has vanished, white fish, chicken, sweethread, etc., should be taken in preference to the stronger forms of animal food.

The whole question of rhenmatic fover is beset with difficulties, owing to the opposite opinions that prevail as regards the best mode of treating it, and the complications that may spring up in its course. It behoeves us to provide against the latter difficulty by attacking the inflammation of internal organs rigorously, and without loss of time, by subdaing pain, and therefore preventing exhaustion, and above all to enforce such rules of living as shall modify that state of constitution favorable to the development of lactic acid in the blood, which favors the disease, promotes its relapse, and encourages its continuance.

We may repeat that it is well to make the alkaline and chalybeate treatment overlap. Thus the bicarbonate of potash may be continued some time after the sente symptoms have passed away, combining it with the ammonio-citrate of iron.

During convalescence we cannot overestimate the importance of maintaining the warmth of the patient by suitable clothing, and by guarding against cold.

Gost.—Although gost does not occur, as a rule, before the age of puberty, it has been met with in young children. "Sir C. Sendamore was assured by a gentleman whose mother labored under this unlady, that he was attracked in the great too at eight years of ago, and medical friends have informed use of cases having occurred at a still earlier period of life. For my own part I con-

fees I have not seen a case of true gout, that is, an articular affection implicating the great tee, in patients much under the age of twenty."

Trousseau calls attention to the fact of an astimatic Moldavian boy, aged five, having a characteristic fit of the gout in the bog toe, and that it was the only instance he had ever seen at such an early age. We find urine laden with arates, scalding and exceeding the external parts in young diddren, where fond and foolish parents give them too much meat, under the impression that this will make them strong.

Rickers is a constitutional malady manifested by depraved nutrition, and an alteration in the shape and composition of the bones. It is "the most common, the most important, and in its effects, the most fatal of discuss which exclusively affect children" (Jenner).

"Rickets," according to Holmes Coote, "though not unknown to the ancients, seems to have been scarcely recognized in Northern Europe till the beginning of the seventeenth century, when it spread over England and other European countries."2

We find on the authority of Whistler, Glisson, Bate, and others, that when the disease first appeared in the western parts of

I St. Bartholomew's Hospital Reports, vol. v. p. 125.

England, at the period just alluded to, it was called the English malady." A term still remined in Germany, at least in the lecture-room, at the present day.

In England, Holland, and some districts of France, it is now one
of the commonest diseases of children. It is occasionally men
with among the rich, and there who are reared in lexury, but it
occurs more frequently among the poor, and is best studied in
hospital practice. It may be witnessed among strumous and tubercular children, but whether this is accidental, or whether rachitis
holds any direct relation to them diatheses, or is a special diarbests,
is a matter not yet settled. Opinious are divided on the question.
Certainly we often see rickets occur independently of struma or
tuberde. It is not, strictly speaking, a disease of the osseous
system, but one of malnutrition, and it belongs to an unhealthy
state of the constitution. "Rickets differs from scrofulous affections in this rospect, that while frequently associated with inflammatory conditions it is not essentially an inflammation."

Rickets is a non-febrile unlade, and sufferers from it have a bodily temperature according to some authorities a little below the normal. In twenty cases under my care, I found the morning and evening temperature so nearly normal that the difference was not worth notice. The features which indicate the affection are now very well recognized, owing to the clinical researches of Kollikor, Virghow, Jenner, Geo. Volkmann, Rokitansky, Holmes Coote, and other authorities. There is, in the first place, always more or less enchexia, the child never looking thoroughly healthy. The head in some cases is markedly deformed, and looks unusually large; but this is to some extent deceptive, because the face is so shrunken and imperfectly developed that it makes the upper part of the head look larger than it really is. In seventeen cases of rickets, the average age being 4.72, the average circumference of the heads was 21,22. In an equal number of non-rachitic childron, with an average ago of 6.05, the average circumference was 19.85.) The bones of the face grow more rapidly in children than the bones of the cranium; on the other hand, in overgrown much

[|] Discussion on Sirkets, Pathological Society, The Lanest, 1889, vol. 15, p. 1617.

or giants, the skull appears small and the forehead low, because the house of the face, like those of the limbs, have increased out of all proportion to those of the cranium. In rickets, nutrition and growth are checked, hence the face is small." The satures are depressed, and feel open when the hand is passed along them; the fontanelles remain unclosed, often to the middle of the second year. The bones of the granium become abnormally thickened, and the whole skull appears flattened at the vertex, and also at the sides, so us to lose its vaulted form and become boxlike. The head is also long and broad, and the width between the eyes is increased. The size of the cranium is therefore large, the satures remain open, and the parietal and frontal bones are largely developed. Between the ill-developed eranium and the equally ill-nourished brain, there is often fluid, simply filling up the space, and not the result of any inflammatory effusion. Hence this condition has been termed " spurious Apdroupholus." In rachitis the cranium is frequently unsymmetrical, a matter worth attending to in diagmorie.

The next characteristic feature of rachitis is found in the osseons walls of the thorax. Owing to the softness of the rile (for the imperfect essification of certain boxes is a pathological feature of this discuse) they yield to the external pressure of the atmosphere during impiration, and hence become flattened laterally and bent inwards; a transverse constriction is often seen at the level of the junction of the stermum and ensiform cartilage, due to the great difficulty of thoroughly Elling the lowest part of the lungs with air. "A second cause is the outward pressure on the lower ribs, caused by enlargement of the liver and spleen, often present in these cases; and a third (which seems rather theoretically probable than absolutely proved) is the laward traction upon the curtilaginous extremities of the ribs by the attachments of the diaphragm. The result is a constriction of the chest, much as though a string had been tied round it below the heart, whilst its apex is distended. Except in very severe cases, this deformity of the chest may be expected to be officed as the child recovers from the constitutional taint."+

In a rickety child, under my care in 1874, aged 11 years, with

^{*} See Mr. Shaw's Observations on Lateral Currentum and Bickets, Release's System of Surgary, sal. s, second edit., p. 871:

⁴ Surgical Treatment of Children's Discours, by T. Holmes, 1868, p. 343.

congenital hypertrophy of the heart and mitral disease, the whole left side of the sternum was rounded and elevated, and extremely convex, whilst the thorax generally, from the amount of emphysome present, was very barrel-shaped and prominent. In a rickety loy, aged nine, under my care in 1878, with mitral regurgitation and hypertrophy after rheuniatic fover, the eardine region was also very rounded and elevated, but, as in the former case, there was a considerable depression or groove running backwards longitudinally from the sternum below the nipples-a groove arising not so much from deficiency of air entering the chest, as from the softening of the bones and their tendency to fall inwards. The common changes are a lateral flattening of the chest, and a promisence of the sternum-in many cases, instead of being nearly circular as in health, it becomes triangular, and the patient presents the wellknown appearance of "pigeon breast," This condition is alluded to under chronic enlargement of the topols."

From the weight of the body the bones of the extremities yield, and the ligaments, bearing an unequal strain, cause the articulations to become distorted, and hence we meet with weakened joints and how-legs; the femur and the tibia are heat forward, the arch of the foot is destroyed, while the outlet of the poiris is narrowed. The limbs become so weak that a child of four or five years of age may not be able to walk, and if it can, it will fall down on meeting with any obstacle in its way. The benestoo, from being soft, readily fracture from slight blows.

The rils and long bones undergo enlargement, and become soft, spongy, and light, whilst the parietal and temporal bones also become thick and spongy, and the vertebral column often yields and becomes curved. The gravest result of the osseous icsions of rickets lies in the ill-development of the pelvis, the cavity of which may be simply narrow from undoutrition of its bony walls, or absolutely deformed, from the softened bones falling in and narrowing the brim. Hence follows in after-life a frequent cause of difficult labor in women; and even in the mule, the extraction of large calculi during lithotomy may be impeded by mehitic deformity of the pelvis. In the case of a boy, aged three years, under

^{*} See Chap. X111, p. 159.

⁴ The large splets or "gross stick" fractures Departs in rickety children are well known to the surgeon. They would involve the radius and the class, but are not rare in other long forces.

my care, both clavicies atood out at a sharp-pointed angle in the centre, as though they had been fractured and badly united. The lower ribs were nodulated where they joined their cartilages, and pressed out in a fantike shape from the enlarged viscera beneath; the upper part of the chest was narrow and contracted, the axillary and infraclavicular regions shrinking in, the spine was curved, the scapake were deformed, and the joints of the larger articulations so loose that they could be twisted in any direction without difficulty.

But the most pathegramonic symptom is the "row of heads" along the junction of the ribs with their cartilages, caused by aight unlargement of the ends of the ribs; this has been termed "the rachitle garland." Dr. Hilton Fagge states that "the enlargement is often much more marked on the pleural side than towards the surface." The articular parts of the bones of the extremities enlarge, causing a "double-jointed" appearance very conspionous at the wrists, due to the enlargement of the epiphyses.

Rickety children are short and of stanted stature. This would appear to depend on an arrest in the growth of the bones; dentition is delayed and irregular, the teeth not appearing in some cases till the differenth or twentieth mouth. In a case under my care in 1874, a child, said to have been three years old, had no appearance of a tooth. In a case of well-marked rickets in a loy, "the first tooth did not appear till be was four years old." The teeth are small, black, ragged, and pointed, they done early and soon fall out.

The constitutional symptoms are very marked. The children are pullid, with prominent veins; they shrink and fall away, and become thin. There are thirst, accelerated pulse, and flushing of the face at night, with broken sleep in all aggravated cases. Fret-falness and irritability are common. Some children almost cry when looked at, and are very timid and alarmed when approached. Such cases are sometimes followed by aquinting, defective vision, and hesitation in speech, which gradually disappear as the general condition improves. Headache after exertion, or inability to take food, is a common and persisting symptom. The child yawns and

^{*} Discussion on Bickets, Pathological Society, Nov., 1888.

⁸ Stimer's Diverses of Children, by Lawson Tair, 1874, p. 222.

sighs repeatedly in the daytime, puts his hand to his head as if to remore something, and then closes his eyes and falls off to sleep with one or both eyes half open, for a few minutes, easily waking up again from any noise or disturbance, and attering a distressing cry. If toys are offered to appease him, he angrily tosses them on one side, and refuses to be friendly with those who have shown him uniform kindness. These symptoms may of course be seen in cerebral exhaustion from other causes, and they are probably rather more common in true hydrocephalus than in rickets.

Should an oraptive illness, as scarlet fever or measles, supervene, the rachitic condition becomes aggravated.

The abdomen is usually large" and distended. The Germans call it Fractions's (Fraglelly), which accurately describes the uppearance; the liver may be felt projecting sharply below the ribs, and the spleen is often very large. The lymphatic glands may a emetimes be falt enlarged and indurated in the neck, groins, and axilla. Children in some cases have a sallow, greenish, or chlorotic tint. This was very noticeable in a little girl I saw, who was suffering from tubercular disease in the lung at the same time.

The head becomes unusually large, and perspires remarkably; beadlike drops may be seen standing on the face, whilst the trunk and limbs are hot; the volus are prominent over the tomples and forehead, and sometimes in the neck and thorax. Occasionally the carotid arteries pulsate strongly, and the heart's action is irritable and excited; but these symptoms are absent in some cases marked by great deformity, while found at other times in less-pronounced cases. The child kicks off the clothes at night, and exposes his limbs. These are among the earliest symptoms.

The appetite is capricious, and there is oppossion and unessiness after food. The motions are like those observed in some forms of diarrheas (lientry), being early and whitish; because the food

[&]quot;The abdomes is very large, and often appears recovered by distanced when compared with the sources and disported close. This enlargement of the belly is the to depression of the displacing and distributed capacity of the therein, which since down the lives and spinon below the lared of the ribs, to increased shallowness of the policie, to the fieldly condition of the abdominal number favoring the accommission of flates generated by the dispostre demagnessed, and in some cases to arread increase in size of the liver and spices."—Wantey District of Children, by Eustane Smith, M.D., 24 eds., p. 113.

passes through the borrols partly mehanged, the digestive functions having exerted little influence upon it.

According to Frerichs, both the liver and spleen, in some cases

of rickets, are affected with amyloid degeneration."

Dr. Dickinson regards the smelling of the abdominal organs as much a part of rickets as the changes in the bones, and he believes the two to be closely analogous. The sphere, liver, and lymphatic glands become enlarged, the sphere most, the mesenteric glands least so. "There is no new growth or deposit, only an irregular development of the proper tissues of the organs. . . . The earthy salts would seem to be diminished in the viscera as in the bones."

The wrine may contain phosphates and mates, but it is usually clear and pale, even when the appetite is most morbid. When there is diarrhean the motions are green, slimy, and offensive, or deficient in bile; and it is in these cases with chronic dyspepsia that the urinary secretion is most affected. In twelve consecutive cases of rickets admitted under my care at the Samaritan Hossital, I found the urine of acid reaction in all; five contained urate, and in three of these the deposit was very copious; two contained phosphates, and the remaining specimens were clear and normal. The highest specific gravity was 1030, the lowest 1020. "The phosphates are more abundant than in health, and a considerable sediment of exalate of lime is not unfrequent; and it has been observed that urinary calculi are frequent in rachitic children." (Copland.) My colleague, Mr. Alban Domn, in 1877, removed an exalate of time calculus from the bladder of a riokety girl, who was admitted into the Samaritan Hospital under my care with symptoms of vesical irritation. Large quantities of urie mid crystals have also been noticed (Hilton Fagge).

The swellen joints and distorted limbs are very painful. The little patient screams even when lifted up gently, which is probaley due to tenderness of the periosteum, where moriod changes are going on; it is subject to slight muscular spasms, clenching its hands tightly, and prefers to sit and lie about instead of joining in the play of its companions. These spasms may be taken for elight convulsions from carebral disease, especially if there he malformation of the skull, which has been erroneously attributed to true hydrocephalus.

^{*} Discuss of the Liver, New Sed. Soc., 1801, vol. 7, p. 175.

⁴ Discoulm on Rickets, Pathological Society, The Laurer, 1880, vol. 7, p. 235.

¹ See Chap. XXIV, p. 264, On Diseases of the Urinary Organs.

As regards the state of the intellect, rickety children are generally dult and stapid, and in some cases there is an approach to idiocy; there is lethargy in all their movements and actions, and they do not exhibit the preciseity of the tuberculous. Their powers of memory are defective, and they have a difficulty in nequiring knowledge; even when the desire is great they fail under the strain, and headache, restless nights, and exhaustion are common manifestations of the constitutional taint. When preceity of intellect is shown (which I think very rare), the explanation offered in that the open sutures allow the brain to expand, and its circulation and development proceed more rapidly than when the cranial bones have been unyielding; but this does not seem to me a satisfactory solution, for when the head is dispreportionately large, my experience is in favor of a tardy and not a precocious development of the mental faculties.

Conses.-Parents from constitutional infirmity, excesses of all kinds, and living in crowded and unbealthy localities, impart a general debility to their offspring, which favors the development of scrofulous disease, and in a less degree, of rickets. Early marriages of the artisan classes, and long hours of labor possed in overcrowded and budly-ventilated workrooms, are powerful factors in proceeding the disorder; for, in addition to the physical exhaustion of the parents, there is also a mental disquietude which has a similarly exciting tendency in the development of rickets. When, as too frequently happens, the children of such parents are not properly fed, or a farinaceous diet takes the place of the maternal milk, or they are prematurely weamed and neglected, then rickets is invited. Rickets is intimately associated with had feeding and faulty assimilation. According to Mr. Hutchinson, it is a diet disease, defective food being probably the main cause. In 12 per cent, of Dr. Baxter's cases faringcoms food of one kind or another had been given before the age of twelve months." "Whatever external or extrinsic circumstances are favorable to the fornution of watery blood (hydraemia) in a child, seem favorable to the development of rickets."+

Though rickets is a disease peculiar to infancy and very early life, there is evidence to prove that it is sometimes congenital. From constitutional vice of the parents it may show itself in the

^{*} Diameter on Elekets, Pathological Society, the Lancet, 1860, vol. ii, p. 1967.

[#] Rickets, by Dr. Ankers, Baynolda's System of Medicine, vol. i. p. 800.

offspring, and cases are recorded where it has attacked the futus in utero." But the evidence is not very confirmatory of such a fact. Hilton Fagge and Dr. Baxter are of opinion that an infant is never born with so called "fetal rickets." Rickets would appear to be most common up to the second year. It is care after the period of the first dentition in healthy children. "Rickets," says Holmes Coote, I "commences at the time of life when the growth of bone is most active, namely, in many about the first or second year." According to Guerin, "in 346 cases the disease commenced 95 times in the first year, 176 times in the second year, 35 times in the third year, 19 times in the fourth year, 10 times in the fifth year, twice in the sixth year, extending to the twelfth." He mentions that in three instances it was congenital. Mr. Stanler reakons the most frequent period from the eighteenth to the twenty-fourth month 2 It is common in damp and cold climates, where children are not enough in the open air, and hence it may be that the disease is of greater frequency in northern than in southern latitudes.

There is often a hereditary history of phthisis and brain disease. Three children out of five in one family I heard of were all rickety, and died of mesenteric disease and convulsions. One case come under my own notice, a lov who was a twin, agod five years, was admitted under my care at the Samaritan Hospital, in June, 1877, with a deformed chest and loose joints. I received the following history: His mother was delicate, and there was phthisis on the father's side of the family. The child had a convulsion during delayed dentition; since then he had been losing flesh, and was weak, irritable, and spiteful. His appetite was ravenous, and he was never satisfied with the food given him. He brought up a great deal of blood, and though the evening temperature reached 102.6° and the pulse 140, no organic change could be detected, After a few days he began to whoop, but the temperature gradually fell to normal, and the cough subsided; the belly was large, the teeth black and decayed, and there was ulceration of the gums, He left the hospital much relieved.

^{* &}quot;Rachtin is unsettings developed in the Sotra whilst yet in its matter's would, even when her health does not appear changed. The masses of parhological anatomy contain account skeleness of those whilsten mehitic from birth, "—M. Tourbut, On Biscop of Enjants and Children, 1855; manufaced by Peter Hincker Bird, F.R.C.S.

¹ Loc etc. p. 1018.

Whatever reduces the general strength, or interferes with digration and assimilation, may induce rickets. "Thus it is particularly remarked among the children of the poor, who are weaned early, and who are before the proper age placed at the family table to be fed with soups, broths, vegetables, meats, etc." (Bonehut.)

The rickety condition is associated with general debility, and is often complicated with broughitis, pneumonia, whooping rough, the emptive fevers, tubercular disease of the thorax or alsonien, laryogismus, and hydrocephains. Any of these disorders have an unfavorable effect upon the progress of the malady, for whatever reduces the general strength and weakens the constitution is retain to retain recovery when favorable symptoms have commenced.

Vogel believes that constitutional syphilis in the perent may muse rickets in children, and he is also under the impression, which I think cannot be altogether denied, that rickets is some times bereditary. "In these cases the father and mother usually display the peculiarly shaped rachitic head, with its boldly projecting unberosities of the frontal and parietal hones." Of 100 cases of cranio takes collected by Dra. Barlour and Lace, 70 showed a nurked degree and 30 a slight degree of the affection. There were proofs of syphilis in 42 instances, 35 of these being among the well marked cases of cranio takes. The authors came to the conclusion that syphilis was the largest factor in the production of cranio-takes. It would seem that the connection between cranio-takes and rickets is very close, and that both affectious may originate in syphilis.† M. Parrot believes syphilis to be a cause of rickets.

The diagnosis of this disorder is not difficult. The diathesis of rickets may be confounded with that of tuberculosis and syphilis, yet their local distinctive characters are clear, and can hardly be mistaken when carefully compared with one another. The general symptoms are different, the progress of the disorder is different, and the changes in the hones are absolutely pathognomonic; but since tubercular and syphilitic children may become rickety through a want of sital power to carry on healthy nutrition, these disorders ought not to proclude the idea of their occasional protents in common. We have already seen that they do occur with rickets, and that the existence of either may induce rachitic

^{*} Vogel, Discouss of Children, 1874, p. 532.

Pattickey of Bickets, Rev. Mod. June. November 20th, 1880.

changes. I have seen a few instances. Tuberenlosis is more hereditary than rickets, but the latter disease is, nevertheless, very often transmitted from parent to offspring. An important point in the diagnosis from hydrocephalus is that the fontanelles are depressed; ther do not rise above the level of the rest of the scalp, and the opening is simply due to an arrest in the osseous development. The antero-posterior diameter is longer than in hydrocephulus; whilst in the latter affection the head is wider, and the face smaller. The change in the articulations, the large joints, the headed ribs, and the alteration in the contour of the thoracic walls, are all distinctive marks of rickets, which show themselves early, and cannot be mistaken for any other disease. " It is strange to see a little chifd sitting placifly on the bed, without moving for hours together-its legs placed so as to escape pressure, its spine bowed, its head thrown backward, the chief weight of its body cast on its arms; and to know that, notwithstanding the apparent calm, the tiny thing is indeed lighting the battle of life; for it is striving with all the energy it has, to keep in constant action every one of its mascles of inspiration-endeavoring so to supply the mechanical defects of its respiratory apparatus, due to the softening of the ribe. It wants no toys. It is the lest of children if you only leave it alone; move it, and you inflict pain upon its tember frame; show it the horse or the doll that was once its delight, and it turns away its head, or stares varantly; to notice would divert its attention too much from the performance of those respiratory movements which are essential to its existence. "a

Morbid Anniony.—The composition of the bones shown a deficiency of lime salts, and an increase in fat, watery elements, and carbonic acid. The bones are soft, light, and easily bent or broken. They contain a deficiency of earthy salts, because those saits have never been deposited in them; just as in softities or on the bones are soft, because their earthy salts have been removed by absorption. The language are enlarged, and there is a great thickening of the periostems. The malautrition of the system interferes with the gradual conversion of the deeper layers of the periosteum and articular cartilage into home; the bone when formed is imperfect, and softer than it should be. The morbid condition of the osseous system brings about viscaral changes, especially in the thorax,

^{*} Bickets, by Sie W. Jenner, Bart., Med. Times, 1860, p. 415.

where respiration is so much impeded, but special changes in the internal organs due to rickets have not been very clearly made out. The wrists are the first parts of the body generally to show these changes, the culs of the radius being large and distorted; and then come the sternam and rike, often irregularly projecting and fattened.

Dr. Goodhart has noticed the blood in many cases of rickets to be deficient in corpuseles in some and in coloring matter in others.*

In mild cases rickets is capable of recovery and care, the disease being arrested as the general bealth improves; but there will be no chance of this whilst the first destition lasts. The softened bones may become firm and consolidated, but the deformity remains for years or through life. Ultimately the distortion of the long bones is in natural course remedied by their concavities filling with osseous buttresses.

If disease of the Image cosme, and the state of the theracic walls leads to imperfect expansion of the pulmonary lobules, emphysema or chronic solidification of the lung-tissue may arise, and cause dyspoon and chronic catarrh, which are apt to slowly wear out the child's strength. Bronchitis, when at all acute or recurrent, is usually fatal to rickety children; the ribs fall in with the increased respiratory efforts required, and the feeble heart cannot overcome the blood stasis in the lungs. In one case under my care, where the constitution was lowered by convulsions and laryngismus, the infant, seven meaths old, died from spasm of the glottis. Taryngismus stridulus is always associated with rickets. "I have seen acute rickets twice fatal in children affected by constitutional syphilis."

Treatment.—In attempting to care, or arrest the discuse, the first and most important point is to ascertain the cause in operation which has produced it. If it has appeared during the time when the child is still suckled at the breast, it may be that the mother or the nume cannot nearish it, and then proper food must be supplied. To speak generally, it may be said that the victims of this disorder should be at once supported by plain and simple food—such food as can be assimilated and easily digested, according to the age and strength of the sufferer. Milk should

^{*} The Lancet, 1881, vol. 1, p. 40.

[!] Seiner's Discous of Children, by Lawson Tait, p. 211.

enter largely into the diet at all stages. If the child is an infant, and the mother's milk is good, it should be kept at the breast for the full period; if it has been wearied, and is not more than two years old, there is no better form of matriment than a plentiful supply of good cow's milk. Beef tea, or other animal broths may be given according to the discretion of the physician.

In the south of France it is formal that puppies fed on human milk become rickety, and recover when again fed on their mother's milk. It has been proposed to try bitch's milk for the treatment.

of rickets in the human infant.

Pure bracing air and warm clothing are important, and a senside residence, when it can be obtained, will improve the general outrition. When there are no contraindications such children should be out of doors in the daytime. These patients should be on mattresses instead of soft beds, and the pillow should be an arranged that the head does not sink into it, as this is certain to increase the restlessness and aweating. To arrest the exhausting perspirations, the head may be douched with cold water night and morning, and the body quickly immerced in a tepid bath containing Tidman's sea soft.

The tineture of belladonns is useful in combination with Iron to

uliay swenting.

The hypophosphite of time bisenits prepared by Van Abbott, Princess Street, London, at the suggestion of Mr. W. Adams, may be given with advantage. Each bisenit contains five grains of the hypophosphite of time, and one may be taken three times a day.

If the bowels are deranged, and digestion is not satisfactorily proceeding, it will be advisable to correct the disordered state by a few grains of blearborate of soin and rhuburb, or sulphate of potash and rhuburb (Form. 84). It is sometimes necessary to give a grain or half a grain of calonic, or two or three grains of gray powder. In this way the stimy or pasty motions will be altered, and the evacuations be rendered more natural and healthy. Some caution is required not to mistake the whitish motions caused by undigested milk for the absence of tide. Mercurials and alteratives, if prescribed, would do an infinity of harm, and we should trust in such cases to giving milk in smaller quantities for with limewater, and such simple remedies as will correct

flatulence and acidity, or we must even suspend the milk altogether for a time, and substitute weak heef tea and bariey-water.

If diarrhom should be troublesome, a drop of hudanum with an alkaline and bismuth mixture will be very useful (Form. 25).

When there is sickness, high-colored urine, and mental irritability, broude of potassium, with sal volatile and citrate of potash, will be useful followed by quinine in small doses; and later on the citrate of iron and quinine, the ammonio-citrate of iron, the solution of dialyzed (ron (liquor ferri dialyzati) or the symp-of the phosphate of iron, or Parrish's Chemical Food.

"Steel wine, though it contains very little iron, is extremely useful. I think it one of the very best forms for administering iron to rickety children. A temporaful or two of steel with half a grain of quinine, and a drop or two of dilute sulphuric acid, constitutes a capital mixture for such cases. It should be taken just before meals."

I have found this preparation of iron very serviceable when conditiond with arcenic in the formula recommended by Mr. Ernsums Wilson. Arsenic promotes appetite and increases the tone of the digestive functions; moreover, according to Ringer, it is of service in chronic dyspepsia and diarrhora, where the motions contain undigested food.

But coddiver oil is our chief remedy in this disease, and it has taken the place of almost every other. It should be prescribed as early as possible, there being scarcely any complication which prevents its administration. Cough and diarrhous yield to it, and the secretions improve under its steady continuance. It should be given in milk, compge wine, or orange juice, twice a day, after food. I am satisfied with half an ounce in the course of twenty-four hours, and I never exceed this quantity. Dr. Norman Moore mentions the fact that some beagle paps, fed on dog biscuits, som after both were noticed to have their legs beat, their joints en-

Accomposated in a tablespoonful of water value a day after food. For a child from five to ben yours of age.

¹ Hasdbook of Therapeutics, 4th edit, p. 251.

larged, and their ribs bended, but under-cod-liver oil they soon ceased to show any signs of rickets."

Cough must be treated in accordance with the pulmonary complication that is present. Depressing drugs, like antinony and mercury, are never justifiable for the brenchitis and postmonia of rickety subjects, but in place of them, ipcomunula, carbonate of ammonia, citrate of potash, and tenega should be given.

If laryngismus should arise (and the association is not uncommon), then iron, cod-liver oil, and bromide of potassium will be useful, and nutritious food and fresh air will be equally important. It is in these cases, especially if the child remains delicate, that sensir, or even sen-bathing, is so valuable; Yarmonth or Lowestoft in the summer; Clifton, Easthourne, or the Isle of Wight in the winter may effect a more rapid improvement than any drugs.

In many cases, the innetion of cod-liver oil, olive oil, or neats-

foot oil is very useful.

Where the deformity of the joints and bones is great the child should be prevented from walking, and properly adapted splints employed. A bandage, worn around the lower ribs and abdomen, gives great support to the weakened muscles. In the case of female children afflicted with rickets, particular care must be taken to keep them off their feet, until some suitable apparatus has been applied, so as to avoid the characteristic deformity of the pelvis, which would expose them to great dangers should they live to bear children. These deformities consist in a diminution in the antero-posterior diameter, due to the sucremand lower lumbar vertebre projecting teo far forward, and to a further narrowing of the inlet from the approximation of the nectabilia.

^{*} The Cause and Transment of Rickets, 1876, p. 32.

CHAPTER L.

SYPHILIS IN CHILDREN.

HEREDITARY SCIENTIFIC BY ADDRESS AND A STREET STREET, IN THE PROPERTY OF THE P

One of the saddest facts revealed by medical and surgical research is the transmission of syphilis from a purent to an innocest child. However clear may be the origin of the disorder, whatever form the disease may assume in the father or mother, it is now well known that in infancy it appears in a distinct character, differing from what may be termed the adult variety in many points; though it is only of late years that infantile syphilis has been thoroughly investigated.

The manner in which syphilis is transmitted to a child is obvious; and it is now admitted that a syphilitic father may beget an infected fixtus, which infects the mother. Hence healthy momen may give birth to syphilitic children, and they may suffer from secondary symptoms, even though they have never had the disease in its primary form. Inocalation of the mother through the forms has been experimentally proved by Mr. Savory. But, of course, direct infection from the mother is equally possible, and it is probably the ordinary mode by which an embryo is syphilized.

In constitutional syphilis the child becomes infected through the vitiated blood of the parents, or the semen of the father. The symptoms that cuone are altogether different from those which follow secondary syphilis in the adult.

Hereditary syphilis is very rare in the upper classes, even among the children of men who have been avouredly profligate before marriage, and who admit that they have saffered from syphilis. Careful attention to medical advice, and good feeding help to eradicate the disease, or to destroy its property of transmission. The disease must be distinguished from the primary form which a child may contract from a diseased norse, or in vaccination.

Women affected with secondary syphilis are very liable to misearriage; but some surgeons, defective in gynncological knowledge, are too apt to attribute abortion to the existence of syphilis. Still, when a child presents signs of the disease, a history of frequent abortions in its mother is significant.

Intranterine syphilis may, and frequently does, kill the forms, or the child may be born alive with symptoms of the disease. But, strange to say, as a rule, the disorder does not manifest itself till nearly a month or six weeks after birth." At this period the shild, previously well nourished, begins to lose flesh and is affected by constant sauffling, due to some morbid change in the murous membrane of the usual fosses. This symptom becomes very troublesome and seldom fails to attract the attention of the chibi's narso and mother. The "anuffles" is a mane in common use for the complaint. It signifies a kind of coryza, a discharge from the nose of a somi-puratent, or sanguineous nature, which in some cases blocks up the nostrils and prevents the child from sucking. is a very grave condition. The patient is now found to be covered with a dull red eruption in large patches. The spots are of a coppery has on the skin, though sometimes bright, resembling roscola. Large leprom patches, inclined to be dry and scaly, may be often seen at the outer and upper parts of the thighs, and ragged ulcers and condylomata extending in males from the base of the serotum to the anus. There are fissures at the bend of the joints, mucous patches of redness, pemphigus, and even alcerative extherma in some instances where the taint is severe. Large ulcers are semetimes seen on the buttocks and inside of the nostrils in severe cases, and superficial alceration is often present on the fingers and tors. Ulcers or patches of ulceration often form on the mucous membrane of the mouth and the angles are often fissured. In a few weeks the child becomes thin, its skin appears desply wrinkled. and of a dirty soot color where not covered by the cruption. The

^{*} Out of 150 rases urthered by IXday, 131 children pressured symptoms before the end of the second month, 110 had symptoms before the end of ex-works, and sill before the end of the first month. He concludes: "1. That the greater proportion of one breaks of constitutional symbile in newtons children occur before the completion of the first munth of their existence. 2. That when the third month is more pure there is no longer much probability that may symptoms of this hind will manifest these solves."— Aginanto Syphile, p. 102.

color has been said to resemble that of coffee mixed with milk, and this is most apparent in the face and forehead. These children have "the look of little old men." The hair is scanty, the cyclinows and cyclishes being often absent; the shild is affected with "a peculiarly boarse cry," or a modification of the voice not unlike the changed voice of syphilis in the adult. He is restless and frestel, and cannot obtain sleep, particularly at night, because the pains are then more severe.

Vaccination frequently brings out a specific rash in children congenitally syphilitie, who may not have exhibited before that period any evidence of the taint. A very general rash of clurneteristic form and have may show itself as early as the fourth day after the act of vaccination. This at once demonstrates that the taint was not conveyed in the vaccine lymph employed.

An infant in this condition is well known to all medical men who attend out-patient practice at a London hospital. The little sufferer soldom, if ever, fails to exhibit the characteristic external appearances of this disease. The syphilitic affection can readily be distinguished from any other form of marasmus; the souffling and wasting always profominate at first over symptoms of internal decangement. The disease may be followed, but is not usually preseded, by voniting or irregular action of the boucle. When, however, syphilis is empected, but there is no marked rash, mucous inhereles may often be detected around the arms and podends, and designmention of the palmar and plantar entitle generally exists, or scales like those in psoriasis and lepra psel off the hands and feet. One of the most absolutely pathognomonio evidences of congenital syphilis is a coppery blush extending from the arms to the untes; it is found only during the early months of infantile life.

We have been speaking of the external symptoms of hereditary syphilis. The next question that naturally suggests itself is; what internal lesions occur in this malady! But this question is hards to answer, for viscoral symptoms are seldom well marked in these cases. Mr. Holmes, after describing the well-known external signs of hereditary syphilis, remarks: "Finally, certain besions or degenerations of the principal viscora have been pointed out as possible to congenital syphilis; but I cannot say that the evidence on this subject appears to me very conclusive, at any rate,

^{*} Diday, op. cit., p. 88.

these lesions are of little moment in practice, innumels as no means exist of recognizing them before death."

Diday admits the difficulty of recognizing the syphilitic changes, Sometimes the enlarged and indurated liver may be felt through the thin parietes, and peritoneal effusion, amearen, and other symptoms indicating obstruction to the circulation through the organ have occurred; but neither, according to his experience, sor that of Gubler, whom he quotes, has jaundice in any instance been seen. A most interesting case, showing to what extent the viscers may be implicated in this disease, even in an infant of three months, has been described by Dr. Coupland.; It must be remarked, however, that the sole evidence of syphilis rested on the fact that the child's mother had been five times programt; the first born alone surviving. Two children were still-born, once the nother miscarried, but the fifth confinement resulted in the birth of the patient, who " had been to all appearances healthy to within three hours of its death, when it began to suffer from shortness of levath." The viscoral lescons were those seen in tertiary forms of syphills among adults: Large gummats were found in the liver, and a small gummatons nodule was detected in the right long. The cortical portion of the kidners and the walls of the beart were inditrated with small round cells. The singular cardiac complication accounts for the sudden death of the pa-

Dr. Gee observes that the spleen is much enlarged in about onefourth of the cases of hereditary syphilis, and that sometimes enlargement of the liver and lymphatic glands is superabled 3. Whether the relation will hold generally good may admit of some doubt, because it may possibly arise from the eacheetic condition of the system attendant upon the syphilitic infection. Still, there can be no doubt of the frequent association. Wilks and Moxon say: "In syphilis we often meet with hypertrophic enlargement of the spleen."

An infant afflicted with hereditary syphilis is remarkably amenable to treatment, the more so because mercury is not liable to act

Pathological Anscore, by Willis and Morce, 1875, p. 475,

prejudicially on very young subjects, on whom it exercises its antisyphilitle tendencies as well as on the adult. But the mortality. among syphilitie children is known to be high. As they grow older, if they survive, second fresh symptoms develop themselves. The milk teeth are brittle, and very prone to caries. The permanent eacines and incisors develop very characteristic peculiarities, first pointed out by Mr. Hutchinson. The upper middle incisers are the most characteristic in these cases. They are smaller than usual, wide apart, and their edges are deeply crescentic. When first cut small friable tula reles project from the croscontic borders, but these are soon broken off. Desfiness, both from disease of the Lempanum and affections of the labyrinth, is frequent among syphilitie children. Another symptom, also first detected by Mr. Hutchinson, is a disease of the corner, termed " interatified brosstitle. This disorder is almost always accompanied by the characteristic deformity of the teeth. It appears after the fifth year, The corner becomes uniformly hazy, with a few interspersed whitish dots; it is found to be also singularly vascular. According to Mr. Holmes, iritis is a rare symptom of infantile symbles.* There are also to be noticed some prominence of the forehead, flattening of the bridge of the nose, linear cientrices at the angles of the mouth, and the palate pre-enting the form of the Gothio arch.

Primary chances occurring on the genitals of children from direct infection through brutal outrage, or early depravity, do not differ from the same seres seen in adults. They are of interest from a medico-legal point of view. Where a seen exists on the genitals at the time of parturition, a child may become infected, but it is exceedingly rare, and the cridence furnished on this point is by no means conclusive.

Infection from the nipples of diseased nurses, produces in childhood the symptoms of primary, followed by secondary syphilis, without the distinguishing features of the hereditary type of the disease.

Lastly, syphilis may be communicated through vaccination, a

^{*} Surgical Treatment of Children's Dissaus, 1878, p. 351.

I In the testh retime of the Clin. Sec. Trans, will be hard a remodable one recorded by Iv. Dome. A girl, too years of age, contracted applittle from an information was working, through a slight abraviou on for furnism. The discuss was very severy and proved fatal.

chancre appearing at the point, touched by virus from a syphilitle subject. Of course, this terrilos complication suggests great caution in guaranteeing the parity of lymph, as insisted on by Mr. Henry Les. It must be taken from the vesicles not later than the clighth day, unmixed with blood, or any other secretion. Of the manner in which syphilis is propagated by vaccination, it is recorded "that in a district of Piedmont, in the year 1861, where syphilis, if not unknown, was at any rate so rare that the medical men in the neighborhood had no opportunity of seeing it, forty-six children, of various ages, were simultaneously attacked with well-marked exphilis, proceeding in all the cases which could be properly examined, from chancres in the arms, followed by buboes in the axiila; and that all these children had been vaccinated, directly or indirectly, from a single child, who was subsequently proved to have contracted syphilis from a wet-nurse; and, further, that those children transmitted the same disease to a number of children, their wet nurses, mothers, etc., and even to children who nursed and played with them; that the women so infected, in turn infected their husbands; and finally that the discuss yielded in all eases to the usual remedies for syphilis." Several similar cases are recorded.

Dispussion.—The general history of the case, the "smulles," the eruption of the skin, and the sallow purchment-like hue of the countenance, distinguish it from all other discusses. There is not much fear of confounding nouse podendi with veneral phagedons, though dishonest parents might falsely give a syphilitic history to the former complaint.

In respect to progenois, many syphilitic children fall into such a bad state of health that they slowly waste and die. When the nose is obstructed by muous in infants, so that they are unable to suck, the complaint often proves fatal. Then, too, if a child is attacked with an inflammatory or emptive disease, or even a mild form of diarrhora, it is prove to succumb from exhaustion.

Treatment.—Mercury is an invaluable remedy in congenital syphilis, and without it there is no probability of eradicating the disease. It should be employed in every case, and if there he say doubt in diagnosis it should not even then be withheld. Every alght and morning a grain or two of the Hyd. c. Creta should be

^{*} Bargiest Treatment of Children's Discuses, by T. Holmes, 1868, p. 355.

given, to which a little Pulv. Crone Arom. c. Opio must be added, if the bowels are inclined to be loose; or what is preferable, the Pulv. Ipsant. co. Children during the time they are under a mercurial course ought to be well ted, otherwise the prejudicial effects of mercury upon nutrition are apt to be manifested.

The fineture of bark and small does of the perchloride of mercury form a good combination when there is considerable debility and cachexia. Merenrial immedian has some very warm advocates, and among them the late Sir B. Brotie, who controded that mercury, internally administered, soldom cured the patient, whilst externally applied, he had never known it to fail. It simply consists in smearing about a drachar of the Ung. Hydrargyri on a piece of flaunch every night, and applying it round the thighs or arms for the usual period of treatment, viz., six weeks. The child must be well washed before every fresh institution, otherwise treatlesome makes are liable to appear at the seat of application.

lodide of potassium is seldom necessary, for most eases are readily and thoroughly cured by moreurials, still that sait has been used with excellent effect. This drug has cured obstitute alcers about the torque and fauces in children affected with hereditary syphilis. In "interstitial keratitis" the use of iodide of potassium is advisable. When the syphilitic tains has disappeared, and debility is the chief symptom to contend with, the syrup of the holide of iron is an excellent remedy. Cod liver oil is sometimes of great service, given in small doses, with milk and timewater.

When the nostrils are obstructed, they may be springed out with warm water twice a day, and in some cases a mild astringent lotion is useful; but the influence of mercury is generally sufficient, and is most to be relied upon.

For the ulcerations that form on the body and about the nove, sinc ointment, a letion of carbolic acid (1 in 50), or the black wash will be found useful. Of greater service still is an application composed of oxide of zinc and starch, with a fourth part of calomel.

^{* &}quot;A little discussion in the Lynn-Medical Society disclosed the fair that the filllewing equicies were bold by members: A Healthy chaldren can be precessed by discused parents in the intervals of applithin recruioscence. 2 The applithin member should always be made to make her child. 3 Mercurial transmit of the member during parameters may give rise to an efection, apart from the constitutional discuss Mercurial transmits at such times in best confusion by the process of immunion."— The Jimmion Processions, Feb. 1880, p. 115.

The diet should consist of a liberal allowance of milk, and the child should have free access to pure air,

Up to the period of the second dentition, conditions of anemia in the subjects of congenital syphilis are not improved by iron, unless it to combined with mercury.

Vaginal discharges of a muco-puralent character are frequently observed in female children who are delicate, and of a strunous labit. The complaint occurs during dentition, from intestinal irritation, ascarides in the restom, and after scarlatina and other fevers. These discharges are almost invariably attributed by parents to some specific talat, and they sometimes imagine the child has been bratally treated. The symptoms are much less severe than in governors. The complaint occurs in children of a few months old, though it is more often observed in those of six or seven years of age. The disease is obsticate in character, and may persist in spite of cleanliness and the most careful freatment.

The symptoms are reduces of the sulva, and the lower part of the ragins, as may be seen on separating the labia. A thick mucopuralent discharge issues from the vagina, and the source of the disease is higher up than is generally imagined. Sometimes there is no local discomfort, but if the discharge has been of any considerable duration, then the parts are sore and there is pain during mirrorition.

The treatment best adapted to cure the complaint is to well forcent the parts, night and morning, with warm water. When there is much local irritation and redness it should be continued till relief follows. Sitting the child for a few minutes in a hip-bath before going to bed is soothing and comfortable. After this a lead lotion should be applied twice or three times a day. The child should not be permitted to run about till a piece of cotten wool, well aprend out, has been laid between the labia, so that the contiguous sides do not approximate. The discharge is then scaked up by the wool instead of trickling around the perimenm and adjoining parts, which increases the irritation. When the inflammation has subsided, an astringent injection of alum and zine may be employed, and if the disease should prove rebellious to treatment, a nitrate of allers lotion may be substituted, and tonics, cod-liver oil, and see air will be advisable.

The composition of the blood is perpetually undergoing alterations, due to differences in the nature and quality of the food that is consumed, and to the changes that ensue in the functions of assimilation and digestion. Liable, then, as this fluid is to alteration, it may abound or be deficient in one or more of its elements. There may be an excess of blood (Approxima) or a deficiency of blood (assemble). It is with the latter condition that we have now to deal.

Ansemia or spansemia may be defined as a state of the system arising. 1. From deficiency of the volume of blood itself. 2. From a deficiency of the red corposeles in the blood. Other solid constituents of the circulating fluid may be also more or less deficient, and the proportion of water increased. This morbid state occurs sufficiently often among children to justify special notice. It may be termed "exaple assemis" or bloodlessness, there being in other respects no artual disease.

Anemia may be divided into. 1. Active or news amenia, where the volume of the blood is lossened. 2. Chronic amenia, where the red and white corpuscles are deficient, as well as the solid cous stituents of the blood in general.

- Acute ansemia is the condition which results from violent epistaxis, or when severe homorrhage occurs from wounds, nicers, muçous membranes, or internal organs; or it supervenes in the course of an acute disease.
- Chronic ansemia comes on more gradually from insufficient food and starvution. We have examples of special forms of the

ANEMIA. 693

affection where the blood is deteriorated from long-standing debility, general exhaustion, fevers, albuminuria, tuberculosis, etc.

The symptoms of the ecote form are those of syncope, the weakened heart being insufficiently stimulated to action by the diminished quantity of blood pressing through its cavities. There is extreme pallor of the face, feeble or suspended respiration, cold clammy skin, and a small feelde pulse. After a time the patient may show signs of rallying, and the features assume a brighter look; the skin becomes warmer, the pulse returns, he stares about as if in bewilderment, and sighs deeply, or is sick. If he attempt to walk before reaction is re-established the faintness returns, and in grave cases where the homorrhage has been profuse, the face becomes paler and more glastly, the extremities are cold, and the pulse cannot be felt. The patient is incresently restless, tooling about in led from one side to the other, unable to swallow, and incapable of being roused. Convulsious ensue, followed by coma and death if the loss of blood continue. After death, in these cases, the envities of the heart are found empty, and the lungs and internal viscera are pale.

The treatment consists in placing the patient in a recumbent posture, with the head low, as in the management of syncope; and in endeavoring to restore the warmth of the surface by friction, and the internal use of stimulants, such as wine, brandy, or ammenta, if the patient can swallow. A mustard positive applied over the cardiac region and to the calves of the legs will be sometimes necessary. To moderate nervous excitement, and to subdue restlessness and delirium, opium may be needed, either in one full dose or in smaller sloses, repeated according to the discretion of the practitioner. Where the patient is analyte available, brandy

or boof tea may be thrown into the rectum-

Simple chronic and min may result from the neute condition which has preceded it, or it steads on gradually from chronic diarrhum, scanty food, and a deficiency of light and air. When children are confined to unhealthy dwellings, which abound in London and large towns in general, they often present a striking contrast to those who are reared in the pure air of the country. A condition of chronic assemia is often observed in children who are naturally delicate, or who, after being reared in the country for the first few years of their lives, are transferred to London or some other large city, and are placed at school in crowded rooms, and in an impure

atmosphere. In this variety of ansenia the blood is also impoterished and deficient in red corpuscles."

The general symptoms, which may have come on in the most gradual and imperceptible manner, are great pallor of the wkin, muccus membranes, gums, and conjunctiva. The ruddy compleason of health has departed, and the fine network of capillaries is no longer visible. There is debility, with exhaustion, and a tendency to faint after excitement or slight illness. The heart is ngitated, and pulpitates on the least exertion or excitement; the impulse is diffused, and appears to strike against the hand very suddenly, whilst the apex heat can often be recognized outside the nipple line; and the nortic valve sound is sharp and abpormally clear. The pulse is small and weak from deficiency of blood, and exertion or fatigue increases its frequency at once; the tongue is extremely pallid, and usually amouth, but in some cases it is slightly farred, flabby, or even colomatons, with indentations along its sides, caused by contact with the teeth. Intercostal neuralgia and pain over the cardine region are frequently to be observed, as well as a sense of heaviness and weight in the limbs; there is headache, chiefly affecting the forehead and vertex in many cases.† The caretids pulsate strongly, the appetite is imperfect, the lowels are torred, and the secretions seanty.

When extreme anemia in children is attended with less of flesh and symptoms of general eachexia, there are grounds for the suspicion of tubercle, and very often disease of the mosenteric glands, even in the absence of fever and cough. The bloodless condition and waxy tint of these children encourage the idea that some organic lesion has arisen, and what so likely to complicate the anemia as the tubercular description.

Three kinds of corrmors may be heard in amemia. 1. Cardiac murmurs. 2. Arterial murmurs. 3. Venous murmurs.

The physical signs heard over the cardino region, and the great arteries and veins of the neck, are probably owing to the normal

[&]quot;Even "in that irrepresent which when enaggerated becomes armain," as Dr. Carpenser remarks in his Pointyles of Rhenza Physiology, "those is a marked disclusion of the corporate, the names resident in a cubic restinctor falling from 5,000,000, which is the normal annual, a about 2,000,000," This reduction affects the real responses, for the white corporates and fixing are anotherise whilst the water is forced.

F. See Chap. I, On the Headache of Gerebral America, the Headaches, by W. H. Day, M. D., 30 edic, 5880.

ANADILA, 695

relations being destroyed between the blood and the muscular tisese of the heart; the former being thin and deficient in red corpuscles, and the latter having become flabby and lost its tone. The muscular heard are "blood sounds," and do not actually owe their existence to any obstruction in the course of the circulation.

The most frequent cardiac marmor is that heard over the pulmonary artery, coincident with the heart's systole. It is soft, of low pitch, and localized over the second and third left intercostal spaces, where the cartilages join the sternum. The artery, at its origin, is superficial, and near the sternum, so that the sound is easily heard when the blood passes through it. A deep implication, which fully inflates the long and elevates the chest-wall, may cause the second to disappear, but pressure with the stethoscope over the ressel, whilst the patient holds his breath, will increase its intensity. I have seen two or three instances where the long was retracted in adults, and the normary, which were load, disappeared when the long was fully inflated on a deep inspiration.

Similar moreover can be board ever any of the heart's critices in extreme nucleia in children and deficate persons—in the course of the norta, and throughout the cardiac area, or even the entire steronm, but they are generally loudest at the losse of the heart, and are single, soft, and blowing. This single murnaur is readily transmitted through the walls of the heart when its muscular tissue is relaxed, and the blood is impoverished and this.

The knowled stafflet (bellows murmor) is an ondocardial nurmor, and is usually considered diagnostic of organic change. When very soft, and occurring even at the upex in anumic subjects, it may be simply the expression of debility and relaxation of the mitral oridae without any roughing or contraction of the valves guarding the aperture of the heart. Although opinions are not unanimous on the mode of production of this nurman, it accords with my experience that it is sometimes heard in children who are accesses, and whose blood is so watery that it is readily thrown into vibration as it passes along the vessels. If deterioration in the quality of the blood can lead to arterial and venous nurmans, we are bound to accept this as a reasonable explanation in some cases.

Over the large arteries in the neck, and synchronous with the pulse, another soft, single, intermittent blowing nurmar is heard when the stethoscope is applied. These nurmars are common after great losses of blood, but no exact conclusions can be drawn from them alone.

In severe cases of anexqia, where the blood is much changed and attenuated, there may be heard over the jugular veins, just above the clavicles, and especially over the right jugular vein, a continuous hum or "humming-top" sound (truit de diable, as the French call it). According to Dr. Gee, pressure with the stethescope will produce the nurmar in a certain number of cases, but a venous hum in chlorotic persons is independent of pressure, and is due to the austonical relations of the parts concerned." "These venous nurmars are seldom absent in well-marked anamia; nevertheless, ansemia is not to be positively inferred from the more presence of any one of these murmars."

When these symptoms continue for a long time, and the heart is perpetually agitated, some dilatation of its walls is apt to cusus. Among children, the heart's area is frequently increased without nurmur, but in long-standing cases the increased impulse, which is undden and slapping, may eventually lead to hypertrophy, the stroke of the heart after a time isoconing longer and heaving. Although this morbid state is not so frequent among nules as females about the time of menstruction, it is sometimes met with in boys who are brought up in unlicalthy homes, breathe bud air, and are deprived of good food.

The diagnosis of blood-murmurs from those due to organic change may be briefly summed up as follows. In the former case, as we have seen, are min murmurs are either arterial or venous; they are chiefly heard over the base of the heart, and at the pulmonary orifice; and although we cannot state positively the causes on which they depend, we are probably right in supposing that the very soft character of the murmur procludes any likelibood of a roughessed or constricted aperture, which is known to produce a rough, grating, musical, or prolonged nurmur over the situation of particular valves. The presence of a diastolic bruit also would indicate valvular disease. When the nurmur is soft and blowing, and is diffused over the entire cardiac region, fading

^{*} American and Peromion, 1877, p. 182.

^{*} The Science and Practice of Medicine, by Dr. Airken, vol. ii. p. 83, 1872.

in intensity towards the apex, it is due to blood change; when it is localized over one or more of the heart's crifices, and cannot be detected above the third rib, it is presumably due to organic change. Irregular action of the heart, feeble pulse, congestion of the lungs from regurgitation through the mitral crifice, blueness of the flugers, and hypertrophy following rheumatism, also point to organic change.

The following is an excellent example of chronic anemia of a most severe type, lasting a long time without any real change for

better or worse:

G. W ..., set, 9, was admitted into the Samaritan Hospital under my care on October 4th, 1877. He came of a delicate family, and his mother was highly nervous. The house in which he resided was said to be unhealthy. It was very small, and situated immefiately above stables. He began to droop two months before admission, complaining of pain, either in his head, chest, or side, The hos presented on his admission a yellowish, waxy pullor, with dark cyclids and blootless lips, the gums and conjunctiva were very pullid, the pulse was quick and small, the temperature was normal. The heart's area was increased, and the apex heat was below and to the left of the nipple, so that dilatation most probably existed to some extent. A soft murmur was heard over all the orifices of the heart, weakest at the apex, and lendest below the left clavicle. The murmur was not audible at the back. A venous hum in the neck was very distinct. The percussion note was not so clear under the right clavicle as the left, and expiration was longer on both sides than in health, which is by no means uncommon in states of debility. The liver was of full size, but no enlarged glands could be felt through the abdominal walls, nor in the mode.

A mixture containing the ammonio-citrate of iron and Fowler's solution was given three times a day, and eggs and beef ten pro-

stribed as the patient's diet.

On the 30th, without any ascertainable cause, he became very ferceish, and between 6 r.m. and 12 r.m. the temperature fluctuated between 102.6° and 104.0°; the pulse reached 134; the skin was burning hot and dry; he complained of pain in his abdomen, was slok, and wandered when he slept; next day the temperature fell to 100.2° and two days later it was normal.

Mr. Allun Doran examined the blood and found it deficient in

red corpuscies, but the white corpuscies were not in excess, nor were they large nor unusually granular.

On the 15th of November it was recorded that the least thing agitated and excited the patient; he became sick without cause, and a full meal sont up his temperature two or three degrees. Fifteen minims of Liques Ferri Dialyzati were ordered in a tablespoonful of water three times a day.

On the 21d, the report states that his anomia was extreme, he had a chievotic tint, the gums, lips, and mucous membrane of the mouth and conjunctive being absolutely coloriess. There was no confusion of ideas, giddiness, or headache. He had a little backing cough, with some whistling rhought over the front of the chest, but no dulness. The temperature had averaged 98.4° during the providing three weeks. For some days he had been taking half a pint of milk, beef ten, eggs, and two ounces of port wine daily. He was now ordered to take half an ounce of counce of ment three times a day, and the solution of iron to be increased to twenty minims for a dose.

December 21st.—He had improved in strength and general appearance. His friends took him home.

Reshouted February 26th, 1878, feeling ill with severe headache and exhaustion; temperature 193°, pulse 128, respiration 40. The murmurs were leader over the heart and cervical vessels. He had not lost more flesh. Cold sponging was ordered to reduce the folcile condition, and a grain of quinine was given three times a day. In five days, the temperature was normal.

March 4th —A phosphorus capsule, containing grain 1.30, was ordered daily after the midday meal. Orange juice with milk was also prescribed.

5th.—He took his food better, and the pulse fell to 96, but he had a vitiated appetite, desiring the most indigestible and unwholesome articles of diet. The heart was less tremuleus; the apex best was an inch external to the nipple line (dilatation), and the sounds were the same. There was no enlargement of the spicen, liver, or lymphatic glands. When he remained in hed be was tolerally well, but when he got up and walked about he was ill from the fatigue and excitement. He weighed 3 stone 3 pounds (45 pounds)

Two onnes of coddiver oil were ordered to be rubbel into las

body daily, and reduced iron and pepsin to be taken in a powder, three times a day,"

A pint of supercarbonated Schwaliach water was ordered daily.

May 14th — He improved for a few days, and then became worse again—he had been occasionally sick, but the temperature was normal. He had but four pounds in weight since last report. There was dulness below the left claylele, and some harsh breathing. The dulness was sucre perceptible over the left superscapalar ridge; below this and between the inner border of the left scapular and spine the respiration was suffling and tubular. The appetite was poor, the pulse quick and agitated, the face more angular, and there was cough.

The asthesia was so great, and the child so exhausted, that an attack of diarrhon or inability to take food might have induced dangerous syncope, and if he samped this, then the morbid action might have originated tubercular disease. But fatal cases of simple aromia do occur in which to disease can be found after death. The bloodless condition extends over a period of works or months, and no remedy has the least effect in improving its quality. The internal organs are pullful, and in some instances there may be slight effusion into the serous cavities or subcutaneous tissues of the body. "We have now seen several of these cases; the blood resembled pink water, and formed no coagula in the vessels or heart. The latter organ exhibits, in a marked degree, that form of fatty degeneration where the laternal surface, especially the left ventricle, presents the peculiar mortiling from change in the muscular fibre."

October 22d —He went to Kingston-on-Thames in June, 1878, and stayed there two months. He had resumed school, and although very pale, there was some return of color in the lips, and be had gained in flesh. The harsh breathing below the left clavicie had departed, but the cardine and cervical marmors were the same.

The treatment of chronic amounts will depend upon the cause and the condition of the patient. If the strength is much reduced,

^{*} Pathological Anatomy, by Willis and Morea, 1875, p. 635.

and the heart weakened, we should keep the patient as much as possible in the prese position till he has regained a little strength, and the heart is steadier. If this precaution he not observed, there is the possibility of frequent faintings, and even fatal syncope, if the disease has been of long standing, and the nutrition of the heart has suffered.

Foremost in the list of remedies for the treatment of anemia are preparations of iron. They have an astringent, a stimulating, and a touse action; some are irritating to the mucous membrane of the stounch, causing pain and uneasiness when it is weak, and others are easily soluble, producing no unpleasant effects. It is, therefore, very important to make a careful selection when any salt of iron appears to be indicated. In the anomia of which we have been speaking, the ammonio-citrate of iron is one of the best remedies. It searcely ever disagrees, and may be continued for a coke together with the best results. It produces neither pain, constipation, nor sickness, and in my experience, I look upon it as the best blood rostorer we possess in simple anomia. It may be given in syrup and water, with or without a grain of earbonate of ammonia (Form, 95) † This is a good combination where, in addition to the assemic state, the child is depressed and languid. When there is great debility, characterized by a hæmic marmur over the base of the heart, and the fongue is flabby and indented by the teeth, the tlucture of the perchloride of iron with glycerin and mater is an excellent tonic (Form. 95). Half a grain, or a

^{* &}quot;Iron possesses the power of argumenting the number of the blood corporder as well at increasing the homoglobia. This is prefectly effected, according to Dr. W. B. Govers, by the eldersaids of iron obtained iron: In the course of first weeks under the use of this remedy the corporder increased greatly in spanier, followed by recovery of the pitters, who referred from pullet, observers of levents, and giddiness in exercise." — The Nameurica of Read Corporder, The Practitioner, July, 1878, p. 10.

grain of quinine may sometimes be advantageously added to each dose of the mixture.

There are other forms of iron which children take readily snough, and as it is advisable to change the preparation from time to time where the blood remains impoverished long together, we possess valuable remedies in the syrup of phosphate of iron, the syrup of hypophosphite of iron, Parrish's chemical food, steel wise, and the syrup of the iodide of iron. Iron lozenges (Trock, Ferri Redoct.) will be found useful in some cases after the chief meals of the day. They are tasteless, and the mode of administration is most convenient. One grain of reduced iron is considered by Mesors. Squire to be equivalent to five grains of citrate of iron."

In those cases of anismin where children have not jost flesh, but are puffed and flabby, the muscles soft, and the bowels torpid, a mixture containing a few grains of sulphate of magnesia with sulphate of iron, or the solution of the perchloride (Form. 97),† will sometimes rouse the digestive functions, regulate the bowels, increase the appetite, and prove highly benedical.

Belladonna may be given with the fincture of the perchloride of iron when the action of the heart is quick and fidgety. It is of benefit in two ways, it reduces the frequency of the heart's beats, by which it has time to gain tone, and it probably has the effect of counteracting the constituting affects of the iron (Form. 98).2

The supercurbonated Schwaltuch water is an excellent chaly-

heate tonic, improving the quality of the blood in these states of animals, and exercising a beneficial influence over the digestive and nonmilative functions. For hospital purposes, however, it is too expensive.

Bernirious or biogeoble sustante is a disorder first described by Dr. Addhon in 1843. I may refer to it in this place, partly hecarrow it is a form of aniemia which relatively speaking is sente, partly on account of cases being recorded among children. Moreover, it has recently occupied much attention. Dr. Addison termed it "illiquatio anamia," Biermer called it " progressive perafrisse carrier." Practically it may be described as a disease where amenda sets to without any approxiable cause, and is unattended hy glandular or visceral disease, or even by loss of flesh. It peogrosses rapidly, and destroys life in from six to twelve moutle, and is most rapidly fatal in young subjects. It is, however, untilly observed in patients past the middle period of life. Dr. Stephen Mackenzie, in an interesting lecture on the subject, describes a case of idiopathic sammin in a schoolboy, aged 10 years, who died five months after the coset of the symptoms. At first he become white, "like wax," and the pallor rapidly increased, with great perspiration, giddiness, and chilliness. Admitted into hospital two menths and a half before death, he was found to have optic nearitis, and a systolic murmur loudest at the agex. His blood contained very pale red corpusales, some of which were not more than a quarter of the usual size, and of those some were tailed. There was no increase of white blood cells. He died, after several attacks of uncontrollable vomiting, epistaxis, and bleeding from the gums."

A case of idiopathic amenia is recorded by Sir William Gull, in which he states his belief that "the line of merbid action seems to be through the nervous system interfering with the functions of digestion, or, more generally speaking, of hemapolesis."? I think this view is in a great measure the cornect one, looking at the high temperature which is so often noticed in children, the antiques of continued anaemia, after food, fatigue, or excitement, changes in the weather, and so forth.

Simple enlargement of the ceretical symphotic glands along with coverair occurs so often in delicate and strumous children, that

[&]quot; The Lancot, well is, 1878, pp. 757-833.

[†] Trum Path, Soc., vol. aniz, p. 383.

some special notice is needed of its nature. The complaint is exerchingly common in hospital practice. Cold, impaired health, and the britation arising from the exanthenata, and particularly searlet fever and diphtherin, excite the lymphatic vessels, and enuse the glands to inflame and swell. The hyperplasia is inflammatory, the cell elements and connective tissue being increased. The glands or affected may remain for an indefinite time colorged and tooler; then they gradually shrink, and resolution takes place, if the general health and constitution are good. They sometimes give rise to writher pula nor inconvenience of any sort. They occur to children in fair health, who get an occasional sore throat, the evelling subsiding in the course of a few days. If the child is delicate, and comes of a strumons family, we speak of " serofulous" enlargement, so common in the out-department of our hospitals, A gland swells, and romains enlarged for some time; then another gland, or, indeed, several glands, become implicated, the morial process spreading from one to the other, and supportation occurs in them one by one, till they either alcerate and discharge a caseous. kind of pas, or it may be considered advisable to open them. In either case a puckered and ugly sear remains for life. When the anguirating glands are not opened by the surgeon, it sometimes happens that the matter within becomes absorbed, leaving a hand concretion in the neck. These enlarged glands may be seen some times in children who are tuberculous, showing no tendency to suppurate. It is in such cases as these, that the cervical glands remain large, uneven, and irregular in slape, without any tenderness or discoloration of the skin. They are freely morable and ton-adherent. The glands usually affected, are the cerviral, ingainel, axillary, and mesenterie. In the neck, they are often found inflamed and tender from sore throat, dentition, and catarrh,

The treatment varies with the condition of the gland. When the enlarged glands have passed into a chronic and indotest state, they are very obstinate in yielding to any method of treatment. If the source of irritation can be ascertained, it should be, if possible, cured or removed; as eccessed of the scalp, decayed teeth, etc. Then we may proceed to deal with the enlarged glands. The application of a weak solution of tineture of indine night and morning, or slight friction with indine continent, are common and useful applications. I greatly prefer the former. When suppuration threatens, a poultice is necessary, and as soon as fluctuation is detected, a small opening should be made horizontally with a lancet, which will often accelerate the cure, and cause the abscess to contract. But if matter threatens to burrow, the abscess must be laid open freely. The constitutional treatment consists in prescribing good food, syrup of iodide of iron, phosphate of iron, codliver oil. Above all, children suffering from these chronic glandular affections should have the benefit of sea-air if it can be obtained.

Lymphodesome is allied to leukamin. It may be described as a morbid affection of a scrofulous character, attended with great enlargement of the lymphatic glands, and a peculiar deposit in the Malpighian bodies of the spheen. There is either a new growth or hypertrophy of the normal lymphatic tissue. In a histological point of view it resembles leukamia, but it differs from it is that there is no excess of white corpuscles in the blood, and from tabercle in having only a slight disposition to undergo the like degenerative changes. But it may alterate and become the seat of historichage, or fatty change, or essention. Suppuration, which, as we have already seen, is so common in the idiopathic or simple inflammatory enlargement of the carvical glands in young stramons subjects, with which affection lymphadenoma is anatomically allied, does not occur.

The lymphatic glands increase rapidly in size, forming tumors of brainlike consistence, clastic, of a whitish-yellow roles, and adherent in masses. The discuss involves the lungs, liver, kidners, stomack, muscles, hones, and subcataneous tissues, in which a new growth of lymphatic tissue is either infiltrated through them, or deposited as a mass or tumor in the substance of these different tegans.

Another characteristic feature of the disease is the effect it sometimes produces on the Licoid, the red corpuscles being diminished and the white increased, so that in such a case lymphade-

none may be said to produce bucocythemia.

The disease commences gradually in the lymphatic glands about the seek, and after a time it spreads and involves other organs in a similar morbid process. It is associated with failing health and exchexin, and it pursues the same fatal course as malignant growths generally, with which it has a close and intimate conportion.

[&]quot;A case of rapidly fatal lymphadenoma" is described by Dr.

Garlick.* A male child, aged seven, was admitted into the Hospital for Sick Children January 5th, 1878. There was a family history of pitthisis and struma. A large mass of glands appeared on the left side of the neck two menths and a half before death, with rapid deterioration of health; at the last there was asthenia, dysphagia, consistend dysphoen, and diarrhen, with high temperature. On a post-mortem examination, twenty-five enlarged and vascular cervical glands were seen on the left side of the neck, the trached and bronchild glands were enlarged, and there was a large vascular lymphatic gland in the hilus of the kidney; in the spicen enlargement of the Malpighian isodies from new cell growth in the sheaths of the comels; in the liver lymphoid growths, the largest the size of a hemp-seed, the adjacent liver cells in a state of fatty degeneration.

Another case of interest is described by Mr. Macnamara. + "A fair haired, blue-eyed, intelligent lad " had been admitted into the Stepney Sick Asylum. The general health was good till June, 1878, when rapid enlargement of the right cervical glands commenced. There was a history of hereditary tuberculosis. On admission into hospital the glands on the right side of the neck felt like a firm sarcomatous growth, with hore and there soft patches. The giands were also enlarged on the left side. There was neither albuminuria, dropsy, nor lencocytosis. Pleurist came on soon after admission, and he sank from impeded respiration and effusion into the plears, five months after the commencement of the symptoms. After death all the lymphatic glands in the body were found to be hypertrophied; yellowish-gray nodules were found on the surface of the liver, spleen, and base of both lungs. Mr. Magnamura detected remarkable changes in the medulls and periosteum of the bones.

Mr. Alban Doran gives me the following particulars of a case which he closely observed when house-surgeon to Mr. Holden, at St. Bartholomew's Hospital, the subject being a boy, A. P.—, aged 11 years. At Christmas, 1872, a tumor began to appear on the right side of the neck, below the lower jaw. It rapidly grew larger. When admitted into the hospital on June 10, 1873, there was a great mass of colorged glands on the right side, from the chin to the sternum. The whole growth felt lobular, firm under

^{*} Trans. Path. Soc., col. suiz, p. 355.

[†] Thid, vol. xiq, p. 560.

the jaw, soft in the middle, and at the lowest part was a fluctuating projection the size of a markle. The skla over the tamor was red, and a week after admission it became sulfierent to the glands, though when first examined it was quite from Considerable enlargement of the upper corrical glands on the left side existed One gland in the right axida was enlarged. There was impaired resonance and feeble respiration over the front of left lung. No enlargement of the fiver could be detected, nor was there any preponderance of white cells in the blood. On applying a treear to the lowest part of the tumor on the right side of the neck, chocolate-colored fluid escaped, consisting of red corpuscles with noncross white blood-oalls. The tumors rapidly increased; for two nights (June 28th and 29th, 1873) Is suffered from dyspours. Late in July the tumor on the right side olcerated, and hemorrhage followed, shooked by cold. This tumor at length sloughed away, the patient became extremely emaciated, and died on September 10th.

Post-mosten Econometer.—The tumor on the right side was reduced to a flaced bug of doughs extending from the zygoma to the clavide. The tumor on the left side was smaller; the upper portion rescribed on section an ordinary enlarged gland; the remainder was softer, very vascular, and deep red. The broughtal glands and one mesenteric gland presented the same appearance, being red and almost pulpy. The splere was very pulpy, the size of a small orange, and deeply lobalated. The glands in the transverse fiscure of the liver were pule and slightly enlarged; the heart, lungs, liver, and kidneys were normal, but the left kidney was indurated by the enlarged spices, and slightly congested. There was intrascoption of about two inches of ileums.

The treatment consisted in the administration of cod-liver oil, and ferriginous tonics. Dr Gowers relates two cases where the blood-corpuscles in this disease increased 20 per cont. during the administration of phosphorus.

Leave-otherica Consequents-levkomia of Virolautt is occurrently

[&]quot; The Noneration of Blad Coquedes, The Frantitions, 1878.

I do printed out by Dr. Hagter Branct and Dr. Parker, Irakemia "white blood" is use a good term, because if the blood by drawn from the annalitie out. Lemongtherain; hereby white, serry, colls and man, blood—whitecost! Stood, expresses the true pathological fact, via. that the blood absumbs in orderless companies. Principles and Frantice at Medicine, by J. Hagter Tennett, M.D., 1877, p. 858.

According to Dv. Michael Force the white cells in Inhaestic are in the proportion of our to ten red.

met with in children. It is a porulise disease of modern discovery, consisting of an increased number of white corporcies in the block, and the formation of a new lymphatic tissue in the spison, lymphatic glands, liver, kidneys, and various other organs of the body."

"It is probable that the power of the white blood-corposoles and lymph-corposoles to form red corposeles is diminished. Possibly also the white corposeles may increase by multiplication in the blood." The disease is unconnected with inflammation, but cometimes associated with tuberculosis, Bright's disease, and conver. It has been estimated by some writers that the proportion of red and white corposeles is about the same, the red being armoged in rouleaux, and the white filling up the spaces between them. Many of the white corposeles are larger, more granular, and contain a single, a double, or a treble nucleus.

The constitutional symptoms of hosperthemia vary in severity: they are, extreme palice and cachexia, a blanched conjunctiva, languor on exertion, frequent vocating, thirst, diarrhoa, or constipation. There is generally enlargement of the spleen liver, and lymphatic glands. There may be oslema of the lower limbs, or ascites, and owing to the changed state of the blood, epistaxis, and bleeding from the gums sometimes happen. The urine is often loaded with lithrates. When the liver is enlarged at an early stage three may be laundlee. Dr. Greenfield describes a case of lensocythismia in a female child, agod four and a half, which proved fatal. The leading symptoms were extreme pallor, and large braised-like spots appeared on the limbs. After death, extensive infiltration of lencocytes were found in the liver, kidneys, and heart. In this case, however, there was a distict history of erphilis in the father and mother, with the ordinary heroditary symptoms in the intient herself.;

| Trans. Puth. Soc., vol. min. p. 298.

Next to the aption, the liver is next commenty to not discussed in less synthesis.

CHAPTER LIL

DEREASES OF THE EAR.

Proposed in childrens—Presidential of the core in childrens—Children designation—Excellent to respond to the method of the Entertain of the Entertain take—Proposed. Openhances: As common flower distriction of the Entertain take—Proposed information of hyperman, chi.—Biograms ample. At most Proposed of preferable of measurement of preferable of the core—Biograms—General and forced in American American to Management Account to become typical.

[Common and total translations—Appetitus—Measurement of preferables—Artificial normal become typical. Excellent of American and Management. Common description.

Two discusses of the organ of hearing are so far more frequent in childhood than any other disorder of the car that they should be described before all others. These diseases are catarrhal deafness and otorrhoon.

The middle and internal car is very similar in childhood and in adult life, owing to the early development of its structures. The three little auditory ossicles are almost full grown at birth, so that the stapes of an infant is very little smaller than that of a giant trooper in a Guard regiment.

On the other hand, the outer bony structures of the ear are very different at birth to what they are in youth and in the adult stage. There is absolutely no bony external meatus, but a mere ring of bone in the new-born infant, destined to enlarge externally so as to form that cossons canal. Hence, in very young children the membrana tympant is much nearer the surface than in adults. The plane of that membrane, too, is nearly herizontal, so that it lies almost level with the base of the skull, as may be seen on examining the under surface of a fetal skull.

The membrana tympanic cuts off the external meatus from the cavity of the tympanum. This membrane is rescular, and readily conveys inflammation from one side to the other. Hence the frequency of inflammation of the tympanum when its external membrane has inflamed from cold, damp, or some injury on its outer aspect. The tympanic cavity communicates with the pharyux by the Eustachian subs, and is lined by ameous membrane. That canal is opened during every act of availowing. The sound of air rushing into the tympanic cavities can be recognized as two simultaneous clicks, during the act of availowing a little water, and this becomes more manifest when the nose is closed. The presence of air on the inner as well as on the outer side of the

membrana tympani is absolutely necessary for the exact transmission of vibrations. It is doubtful whether the air in the tympanum be of the same density as the external atmosphere."

Frequent attacks of acute coryza, or of sore throat, so common in childhood, cause thickening of the mucous mombrane of the Eistaclasa tube, which thus becomes obstructed. Simultaneous culargement of the tonsils generally exists, but this complication does not much impresse the defect of hearing. The child complains of a beavy feeling in one or both ears, and becomes decidedly deaf. Incipient deafness is often mistakes for duluess of intellect or wilful inattention to the commands of a teacher, and so the poor child is often unfairly redicated or penished. From the tubes the inflammation extends to the tympanic cavity. Pain in the ear then becomes frequent, and through exposure to damp, the sulld inflammatory stage assumes an acute form, with increase of suffering. The blocking of the Eustachian tube causes great external occeavity of the membrana tympani, owing to atmospheric pressure being greater without than within the tymponum. This may permanently damage the membrane.

All those common forms of "cata-rhol denfares"—whether due to chronic inflammation of the Eustachian tubes, or to chronic or subsaute inflammatory processes going on within the tympassiss, may come under the notice of the physician. Some of the most accessary curative measures particularly for inflation of the Eustachian tubes—must be left to the surgeon. But the same general and local measures that are of benefit in tonsillitis and coryza will be required when the ameous membrane of the anditory apparatus is involved. Without them, surgical interference will, at most, insure only temporary improvement. Hence tonies, ced liver oid, weak astringent applications (as in tonsillitis), and fresh air are imporative.

The most troublesome of all diseases of the ear in childhood is purulent inflammation of the tympanic morous membrane, with perforation of the membrana tympani and escape of unlocalthy pas by the external meatus. Circumscribed supportation within the tympanum is very rare. An interesting case of acute critis, terminating in abscess of the tympanum, is related by Dr. Moorhead, in a toy, 15 years of age. It commenced with scate pain in the left car, the temperature cose to 102°, and the pulse to 120.

^{*} See Keese, On Middle-East Donkers, The Lancet, vol. II, 1878, p. 680.

Hearing was impaired, and the membrana tympani became opaque. Under the use of leeches and antiphlogistic remedies, the pulse and temperature fell to normal. The breath was very fetid, and it soon become evident that pass which had been past up in the tympanic cavity had found its way through the Eustachian take into the threat. Three weeks later, the deafness being still extreme, the patient suddenly heard a lend noise in the affected ear, followed by an escape of fetid pus through the Eustachian tube, and the restoration of hearing."

Otorrhon must always be regarded with ampicion; it may lead

to meningitis, facial paralysis, or other grave affection.

Otoerhom often commences us a low form of entarghal deaffices in sickly strumous children. But it also very frequently appears as a local result of great general impairment of health after the examthemata, purricularly scarlatina, and other mente diseases. Floid remarks: "The mucous membrane is liable to inflammations, usually of a entarrical kind, which are analogous with the changes seen in other mucous membranes. The most severe forms are those which are extensions of the inflammations occurring in the moscoss membrane of the fances and pharynx in dightheria. and senriet fever; these pass along the Eustachian tube, and affecting the tymponium with the same severity they do the throat, often work terrible havor there; for not only will they fill it with pus and produce perforation, by inflammation and overdistension of the dram-membrane, but frequently the deeper structures are also involved, so that the periosteum becomes injured, and caries or accrerie of the bony walls ensue, producing in many cases an utter destruction of the organ, if not of the individual. The perils. of meningitis, philebitis, absects of the brain, pysemia, and the like, are all threatening when this most severe form of disease in the tympanum occurs. We may consider it fortunate sometimes when the cavity becomes blocked with a mass of cheese unterial which may become quiescont; though unfortunately remaining as a hidden danger, which at any time may develop into an active centre of infection, and cause a general tuberculosis. This form of discuse is most frequently seen in young children, and it often affects both cars at once; when this happens they generally grow up as deaf mutes."]

British Medical Journal, vol. 4, 1974, p. 343.

f See Chip XLII, p. 841, On Muniquia

² Diseases of the Ear, 2d wild, p. 221.

A child of four, admitted into the Samaritan Hospital, in the automa of 1878, with acute talerculosis of both lungs, was found to have a discharge from the measus on both sides, a few days after admission. Nouse followed, attacking the integaments behind the cars; and after the patient's death the right potrous hore was found to have become nervosal, both tymposic cavities to be full of jus, and the ossicula quite loose. Not a trace of the membrana tymposic rould be found on either side. This case illustrates, in a very aggravated form, the sticlogy and course of storrhors. In ordinary cases, the discharge may last for months or years, issuing through a small hole in the membrana tymposic, but earies or necrosis of the neighboring bosos is fortunately rare.

The constant paralest or muco-paralest discharge from the meatus senders the diagnosis of otorrhea very simple. The discharge often such a diagnosis of otorrhea very simple. The discharge often such a offensively when no discuss of the lone exists. A capious secretion from the external meature above is so unusual, that a free escape of any morbid finial from that passage implies, as a rule, perforation of the numbrana tympani. This complication, or rather, this constant feature in chronic otorrhea, is not in itself serious, as the tympanic cavity thereby becomes accessible to injections.

A purelent discharge from the mentus often gives rise to polypoid growths, and according to the author just quoted, "Polypl frequently occur in the middle our, and are, perhaps, invariably the results of inflammation. Their structure and history vary with the severity of the inflammation, and the parts from which they spring. The most common is the ordinary nancous polypus, of a similar nature to those seen in the nose and more. These spring from the nancous surface, and are formed of soft ceilalar tissue; they contain reduplications of the spithelial surface forming glandlike tubes or sacs. The surface of the growth is covered with ciliated cylinder epithelium, which changes sometimes at its extremity to a mixed or pavement epithelium. More rare are the fibromata developed from the periosteal layer." Aural polypi arise almost invariably from the walls of the tympanic cavity and may easily be removed by Wilde's polypus snare.

The existence of a hole in the metallerina tympani in cases of coplora discharge is indisputable, from clinical evidence and from the anatomical peculiarities of the tympanum. Matter escapes through the least-resisting structures in its neighborhood. In the tympenum the Eustachian tube and the membrane are the least-resisting media for the discharge of secretions. But the tube is, in these cases, almost always partially obstructed, and the membrane, on the other hand, is softened by inflammatory changes, so that it first bulges externally, then yields at one point. This perforation may for some time remain very minute, as though a pin had been pushed through the membrane, but it may be so extreme that nothing remains but a crescentic ridge or elevation at the bottom of the external meature to mark the site of the membrana tympani.

Hinton, speaking of cataerhal inflammation of the meatus, with "more or less profuse semi-paralent discharge," asserts that "ao far as I have observed, this condition is a concomitant of a similar affection of the typoponic cavity. Many cases also of apparent cataerh of the results are really cases of minute perforation of the membrane." Von Trollsch, in reference to what he terms obsonic supportaive areal cutaerh, remarks very positively: "Perforation, or partial destruction of the assusbrana tympani, is always present in these cases."?

Enlargement of the upper cervical glands is a very general symptom of eterrhom. More or less desfiness always exists, but very irregular in degree, for it may be extreme in a mild attack, whilst it is sometimes but slight after destruction of the greater part of the membrana tymponi and loss of the oscieles. It has long been a truism that, if the stapes fall out, inevitable and complete loss of hearing must follow. Still, we must remember that in all things the most experienced men are the most sparing in very positive assertions. And it is well to notice that in this matter Hinton observes: "Whether total desfiness necessarily results from loss of the stapes, involving, as it must do, the discharge of the perilymph from the internal cur, is as yet undecided."

In chronic otorrhom, the pain is slight, as a rule, but occasionally it becomes severe, if the discharge be very copious, and makes to escape freely.

Diagnosis.—The muco-purulent discharge is pathognomenic of otorrhea, but it is necessary to ascertain the amount of mischief

^{*} Holmer's System of Surgery, 5d edit, vol. III, p. 286.

[#] Surgical Discuss of the Ear, tress by J. Hintse, New Syd Soo, ed. Inil.

¹ Loc. jum, etc., p. 314.

existing in any given case. On inspecting the meatus the dis-charge prevents any clear view of the deeper parts. So the ear should first be syringed out with lukewarm water, and the meatus cleared by means of a piece of wool twisted on the end of a quill pen. If the membrana tympani be murty destroyed, the tympunic cavity may then be clearly seen through a speculum, the malleus standing out holdly in relief if it has not fallen out, and the premontory will be covered with bright-red granulations. But nore usually, the membrana tympani can be distinguished vascular in appearance, and showing a small perforation. Yer in many instances the aperture is so minute that it cannot be seen at first. If, whilst the medical attendant looks through the speculum the patient be directed to make a forcible expiration, with his mouth and nose firmly closed, some of the discharge will be seen issuing through the aperture. Under similar circumstances the noise of air rushing through the perforation may be heard when the Eustachian tube is patent, particularly if a tube be placed with one end in the patient's car and the other in that of the medical sticulant, during the inflation of the Eustachian take. In cases of minute perforations, invisites on first inspection, their presence may be suspected by a pulsating movement in the film of fluid covering the outer side of the membrana tympani.

Trestural.-Although otorrises often disappears, after lasting for years, it seldom fails to produce personent mischief to the sense of hearing, and, besides its offensive sharacter, the results may be serious, or even fatal." Fortunately, few local diseases are more amenable to general treatment. Cod-liver oil and strel wine, judicionaly administered, seldom fall to check the discharge. But this benefit is effected slowly by such drugs, so that it is always necessary to remove daily the morted accumulation that already fills the meatus. The ear should be syringed out with tepid water several times daily, at the risk of causing occasional faintness, for the disuse of the syringe involves worse results. A little carbolic acid (1 in 40 or 50) should be added to the water when there is fetor. After the syringing, a few drops of a weak astringent solution should be poured into the mentus. Sulphute of sinc (gr. j to v in 3j of water with 5j of glycerin) is very efficarious. Acetate of lead is objectionable, as it forms a precipitate

^{*} Securi instructive chapter On the Results at Supparative Inflammation, Field's Discuss of the Err, 2d edit, p. 130.

in the ear. Alum may be used for a short time, but its effects must be carefully watched, as it irritates the meature. Strong caustics have been used with great success, but the general physician and surgeon should not attempt to employ them unless be has had unusual clinical experience of car diseases.

When the discharge is checked the cure of the perforation may be undertaken, but not till them. The edges of the sperture should be touched, through a speculum, with a stick of nitrate of sliver. If the membrana tympani be quite or almost completely destroyed, an artificial membrane should be wern. The more simple contrivance of Veursley—a plug of moistened wool—is often very efficacious. Its application is best performed in the

way described by the late Mr. Hinton.

For the cotton-wool I prefer glycerin to water, as it will then retain sufficient moisture not to need changing for four or five days; and in most cases I ald to the conce of glyceria from five to twenty grains of sulphate of zinc. Being rolled up into a small spinile shaped plug, about half an inch long, it may be introduced ofther by a pair of forceps or threaded through a narrow eiter tube: I think it is best to direct whatever form of artificial membrane is used towards the upper and posterior part of the tymponum, so as to touch, if it be present, the head of the stapus. A little pain is sometimes complained of, but if the attempt seccools well the intiest is inimediately conscious of hearing better, and the oction or disk should then be left in sits and the tube or forcers carefully withdrawn. After a little instruction from the surgeon, the patient soon learns to apply it himself, and if care is taken to prevent accumulation of discharge or epolermis, the effect. continues indefinitely, and often becomes, even in cases of otherwire extreme deafaces, so permanent as to render the discontinuame of the wool possible.

Thus, after careful local and general treatment, oterrhous may be cured in a few months. It is always likely to recur during child, a bood and adolescence, and each recurrence must be treated like the original attack. Symptoms of sudden fever-ishness and head-ache, denoting the possibility of intracranial inflammation, may come on at any stage, and require prompt surgical assistance. But this grave complication is very rare, considering the great frequency of oterhors.

Eczons of the anxide in very common in infancy. It is an un-

sightly affection, and enuses great irritation. It is generally associated with recomm capitis, or it may be produced by the irritation of dirt or of coarse scap, or of oterriscal discharge. The best local treatment coasists in the application of equal parts of glycerin and liquor calcis saccharatus. If very obstituate and chronic, a solution of nitrate of silver will prove heneficial. The lotion should be very dilute at first (gr. ij ad 5j), and gradually increased to gr. x or xx to the fluid onnee. A coating of vascline protests the sore car from irritation when the child is taken out of doors. But all these applications are useless when the rach arises from constitutional derangement, unless alteratives be given, and these be followed by touies.

Aboves, or small passales in the account, cause great suffering and irritation. They arise from constitutional debility, or from the irritation of injections, or the presence of dirty wood in the meature. The parents of a child should be directed never to plug the ear except when ordered to do so by the medical attendant. They should also be recalled that the meatur must not be washed out with water, and dried with the corner of a towel forced into it. Well-intentioned mothers and surses often produce curache, inflammation of the meatur, or blocking of that passage by accumulated cerumen, etc., by this mistaken practice. The meatur is naturally meant to be dry, the cerumen constantly falling off in line powder. If it be moistened the cerumen cannot escape; it necumulates and forms a moist, classicy mass. It ultimately dries, sticking fast in the meatur, so that it can only be removed by syringing.

An aboress in the cur is very poinful, and must be treated with warm femoutations, early incision, together with constitutional

remedies.

The skin is supplied with bloodvessels, nerves, and glands, and it performs a most important part as an exhalant surface. It is the common sent of touch and sensation, and it has direct relation with the internal organs.

The skin is much more susceptible in some persons than it is in others, and readily takes on morbid action. Its diseases are numerous and variable, some being inflammatory, as orythoma, erysteens, articarin, etc., and others being of a parasitic or contagions nature. Some are local and others are constitutional, each demanding a separate line of treatment. Diseases of the skin are of such frequent occurrence, and they come before the practitioner so constantly in daily practice that he ought to posses a fair knowledge of their pathology, diagnosis, and treatment.

The skin discuss of children should be looked at from a constitutional point of view, except in specific affections. They are mainly due to malnutrition, to errors of diet, to parasites, and to scratching. I propose to discuss only the most common types, leaving the more unusual ones for the specialist to deal with.

Those discuses of the skin in children with which the practitioner most frequently meets, are:

- 1. Those of the general surface of the body.
- 2. Those of the senip.

The chief cutaneous diseases affecting the body are: Erythema, urticaria, roscola, lichen, poetissis, oczena, Jupus vulgaris, and scalics.

Erythena consists in imfammation or hypersemin of the integument, which disappears on pressure, and of some swelling, arising from the exudation of serum into the subcutaneous cellular tissue. The inflammation is superficial, and bears in a slight degree a resemblance to erysipelas, though it never leads to destruction of tissue, as in the latter affection. "The following are the chief points which distinguish anythematons inflammation: (1) Its superficial character. (2.) Its tendency to invade new tissue, but not to return to that previously affected, in which respect it contrasts remarkably with seconds. (2.) Its liability to attack symmetrical parts of the hody. (4.) The marked tendency there is to slight cutaneous homographic in the course of the inflammatory process. (5.) The very slight constitutional disturbance."

There are only two varieties of crythema deserving notice in a

work like the present.

1. Ergelesso Samplex is that which has just been described.

2. Erythose Notices.—In this psculiur affection eval and red patches, varying frees half an luch to two luckes in diameter, having their long axes downwards, are seen on the front of the legs in the course of the tibia. They more rarely appear on other parts of the body. These patches are smollen and elevated from puffiness of the cellular tissue beneath, and are very tender on pressure. The patches, which at first are red, gradually become of a purple or dark congestive hue, in fact, passing through the stages of an ordinary bruise. The constitutional symptoms are languor, lassitude, headsche, disordered digestion, pain in the limbs, and slight febrile disturbance. In some cases under my care it was distinctly associated with rheumatism, but Dr. Liveing considers the articular pains not unfrequently belong to the disease itself.†

There is a form of crythema due to local causes—crythema intenfrigo, which arises from the friction of opposed folds of skin, and is very common in fat children. It is seen at the upper parts of the thighs, on their inner aspect, and between the nates. The parts at first become red, and then a serdus, or sero-purulent discharge takes place. The treatment consists in the application of a little red lotion, or dusting the part with starch or oxide of zinc powder. "The saliva will often cause crythema around the months of children, especially when cold winds pretail. There is also a chronic form of crythema, which is common on the face and about the lips and noses of children. This variety is also

^{*} Diagnosis of Skin Linemes, by B. Liveing, M.D., 1878, p. 01.

[†] Cip. ch., p. 55.

accompanied by eracking, which is very irritable and trouble-

Produced —In severe cases this consists in rest in bed, with such remolies as correct the general health. Tonics are valuable in crythema nodosum, and quinine has in my experience acted as a specific.

Chilloins consist of a localized crythema of the skin, chiefly affecting the hands and feet, as well as some other parts of the hody most distant from the centre of the circulation, as the nose and lobes of the ear. Among children they are common in the winter across of the year when the weather is odd. The first action of cold is to produce a degree of numbers and insensibility of the affected part, a stiffness in methon, and more or less paller from an impediment to circulation. When reaction is cetablished, itching and tingling are experienced in the part, which soon becomes red, hot, and avoltes. An abrapt line marks the limit of the inflammation. After the shill-lain has continued a few days, the reduces is exchanged for a bluish or livid appearance, in consequence of congestion, dilutation of the capillaries, and slowness of the circulation. A shill-lain may, however, reach another stage.

Mr. Erasmus Wilson has described three degrees of severity:

- 1. The Erythemotous chilliain.
- = The Vericated chilldain.
- 3. The Gangresous children.
- The Erythenolous oblibbin is that which has just been described.
- 2. The resisted or broken chillidain may be a consequence of the former variety, or arise from a greater degree of cold. The itching, swelling, and congestion are greater, and the chillidain is of a dusky purplish that. The cutiele is raised by efficient of serum beneath which forms a vesicle, and, when it bursts, the surface is livid or gray, expecting an observated or sloughing surface. Such chillidains are very tooler and paintful, the child cannot walk, and if the weather be severe and the health impaired, they may last all the winter.
- The Gray a now Chibbain.—In this variety the surface of the skin is destroyed by the action of the cold, gangrene follows, and

^{*} Hendisole of Ster Diames, to Dr. Hillian, 1965, p. 41.

⁴ Discusse of the Skin, 1865, p. 314.

a slough separates. Sometimes the constitutional symptoms are severe, there is great prostrution of strength, and, according to Mr. Erasmus Wilson, the brain is particularly liable to be affected, and the complaint semetimes to end fatally.

Terribuent .- For the ordinary explorations children, a mild stimulating liniment of emphor, ammoria, etc., will sometimes restore the circulation in the affected part, or one composed of some limiment and tinesure of contharidis. Mr. Erasnous Wilson says: "One of the most useful remedies for the above purpose is a liniment composed of the white and yolk of two eggs, two ources of spirits of turpentine, and two courses of distilled vinegar, well shaken together." I have never found any remedy so uniformly successful as quinting the affected parts with a solution of nitrate of silver (gr. x-xx ad \$i) night and morning, and keeping them warm and protected from the nir. The remains and afcreated chilidains are to be treated according to their inflamed or infoloat condition. If infinmed, water dressing will be of service, or a lead lotion; if the sores are terpid, the beaxente of zinc contraont, calumine contment, or the resin clutment, with or without spirits of turpentine, will be demanded.

Uniforms, or nottlerash, is so called from an appearance of the skin similar to that caused by the sting of the common nettle. Wheals form on the skin, accompanied by burning and stinging, and they rapidly disappear without desquamation. They may be round, eval, or irregular in shape, and pule red or dusky in color, Urticaria often comes on after a meal, accompanied with symptoms of indigestion, weight and pain at the epigastrium, nauses or even vomiting, the eruption lasting a short time, and then disappearing to recur again after taking food. The disease is sometimes very chronic and obstinate. "It is not uncommon for urticaria to occur in the course of other diseases, febrile and nonfideils. I have seen it during as well as after scarlation, and occurionally in connection with other exanthemata, and whooping rough."† The disease may be combined with crythema and prurigo.

Greeze. The disease may arise from the stings of insects or fleas, from mental emotion, or fear, or anger, and from certain articles of diet, as shell-fish, lobsters, pork, mushrooms, cheese, etc. Worms in the intestinal canal are said to produce it.

^{*} Op. ed., p. 315.

[†] Handbook of Skin Diseases, by Dr. Hillier, 1865, p. 61.

Treatment.—When the disease is acute, and there is gastric disturbance, an emetic is the best remedy, followed by an aperient. The dist should consist of mutton, milk, bread, and fresh vegetables. Citrate of potash, bicarbonate of sola, and the carbonate of atmostic will be useful. In the obvious form the dist must be carefully attended to, and the general health looked after. Quinine and assente are of use in recurring attacks.

Bonds or recertash consists of red spots of sruption, and is frequently seen in infants and young children. It resembles an ordinary inflammation of the skin, a state of hypersemia in which the capillaries are more or less distanded. There is one form called Russler annotate consisting of red rings with healthy skin between them; when seen in infants it is called Roscola introduce that which accompanies the premonitory fever of various is called Roscola various, and that following varcination Roscola narranse. The disease resembles in some instances wearles, and in others and it is usually limited to one limb, or to the trunk of the hody. It may disappear in a few hours or last several days. It is wanting in the bright scarlet has of scarlatina. The craption is generally attended with itching. Many of the so-called roscolar are only varieties of articaria.

The conses which give rise to the affection are disturbance of the digostive organs, especially in hot weather, drinking cold water when the body is heated, destition, etc.

Thermont.—The digestive organs must be regulated by mild aperious and a simple dist. If the guns are inflamed and tender from the pressure of teeth they should be lanced. Change of air, mild tonics, and sea-bathing are serviceable.

Lichen is recognized by numerous small red papules occurring on any part of the body; but the back of the hands, the neck, and the trunk are the most frequent sites. The affected parts itch intelerably, and at last the papules desquamate and the cruption vanishes.

In Lichen erticates the papules are larger, inflamed, and prominent. They are like the bite of a guat or lug, and the surface is apt to bleed if there is much scratching. "The disease seems to be peculiar to children, and is remarkable for its obstinacy."

Treatment.-This consists in the administration of alkalies and

^{*} Wilson, On Linemer of the Shee, 1963, p. 161.

aperions. For the relief of itching, and to soothe irritable parts, lottons of bonax and hydrocyanic acid with glycerin; belladonna, and hydrocyanic acid, or bicarbonate of soda and hydrocyanic acid are recommended. When the disease becomes chronic, arsenic should be given for some time.

Provisels on legac is not common before five years of age. It is characterized by small white spots which increase in size and then run together, forming white and scaly patches. These parches are nothing more than layers of epidermis. There are notified vesicles nor pustules. The parts below the patchla and elbow are most liable to be attacked, and sometimes the nails. Two forms are described. I. That unattended with itching. 2. That attended with itching, which is often called goody purphists, and rarely most with in children.

The discuse is said to be hereditary. It is often seen in delicate and encheetic young persons whose digestion is at fault; and it is exceedingly liable to retur from time to time. Indigestion, constitutional debility, rickets, and tuberculosis are common causes.

Two/owns. - Remedies both of an internal and external character are needed. A careful regulation of the diet and attention to the bowels are in all cases demanded. After this arsenic, as in many other chronic discuses of the skin, is useful; it nots as a tonic and alterative. The amortitutional offects of the remedy are well known, as quickness of the pulse, leat, and itching of the syclids, dryness of the throat, and a silvery film on the tongue. Sickness and distribute sometimes ensue, and when any of these effects are produced, the remedy should be discontinued, at least for a time. Arsenic should be given after meals, either in plain water or some litter infusion, made agreeable by the addition of a little simple syrup. "Children bear arsenic very well, and one minim of Fowber's solution may be given twice or three times a day to a child of from one to two years old, and the dose gradually increased up to three minima. In the case of infants at the breast, small doses of arsenic may be administered to the mother." As to local treatment this is very important. The scales when abundant should be removed by friction with soft scap and water, after which Dr. Liveing recommends the surface to be dressed with tar chit-

^{*} Notes on the Treatment of Shin Diseases, by R. Limite, M.D., 1815, p. 61.

norst,* and when the skin becomes dry it should be ameared with grease to keep it soft. "A solution of salicylic soid in alcohol (1 in 16), when rubbed over the pseriasis patch, removes the scales in a few minutes, and then prepares the skin for further treatment."† When the joints are crucked and sore, the application of olive oil will be necessary, the limb being afterwards protected with flamed.

Ecrass, which is one of the most common diseases of the skin, may be divided into: I. Acute. 2. Chronic. The neute variety consists in an eruption of small and slightly elevated vesicles, situated on patches of inflamed skin, and attended with severe smarring and itching. It is not contagious, but in a pustular form, ineculable: The fluid contained in the vesicles becomes opaque and thick, then it is discharged and dries into a superficial yellowish scale. The skin immediately surrounding the affected parts becomes similarly involved, and vesicles form on it to follow the same series of changes. The discharge coming in contact with a scratch or sore may produce the disease.

According to the late Dr. Tilhury Fox, resides are not always seen, but their formation shows the "full height of the disease orzona." There is an erythranties eczema, a restrator orzema, а муминову осления, and а рузенбее селения. Не ваух мото осления are almost entirely local, being caused by local livitunts, having scurredy any inflammatory action, and yielding to local remedies. Then there are other cases in which the local mischief is severe; there is a sensation of heat, itching, and huming, the subentaneous tissue is implicated, and the discharge is copious and irritating to the parts around. "In a third class of cases, occurring in young and lymphatic children, there is very free and early formation of pus, out of proportion to the degree of inflammation, as compared with the last form of eczema, indicating a pyogenic habit of body well marked. There is also free crusting, and often distinct svidence of the scrofulous diathesis in the family history. Now, though these now suil then run the one into the other-and there are no hard and fast boundary lines in medicine-yet, on the

whole, the distinctions are clear, and the terms simplex, rubrum, and impetiginodes, accurately portray these clinical varieties."

Children who are subject to occase a are generally pale, this, and imperfectly nourished; the skin is dry and irritable, and the nervous system is wanting in tone. There is also an element of debility about them. In 1872, I had a very obstinate case of subacute bronchitis under my care, associated with chronic eczema, in a child twenty-one months old. The child, who presented a strumous aspect, had all her teeth but two; the lips were thick and bloodless, and the face, back of hands, and the flexures of the joints were covered with an irritating eruption. Under careful medical and hygienic treatment the child eventually recovered, though for some time after, exposure to cold brought on the cruption and renewed the bronchitis. About the same time I saw adelicate boy, aged eight, who had subscate occama and bronchitis of a tedious character. He was treated carefully for two years, and then made a good recovery.

The treatment of scale eczenic consists in the observance of rest and quiet. As articles of diec, milk and water, farianceous food, eggs, etc., should be prescribed. Stimulating food and spirits should be avoided. In the shape of medicines, sulphate of magnesia, with a few grains of nitrate of potash may be needed (Form. 8). A powder of scammons with calonel, or a little of the latter with the compound liquorice powder may be useful as an active purgative. Cold-water dressings, or the lotlo rounds are the best applications when there is heat and inflammation. They should be changed as often as they become dry. If there is great tingling of the skin, alkaline lotions, or the decession of porcy-heads may be necessary. It must be horse in mind that ointments are most useful in the scaly, and lotions in the discharging stage. Fluid applications are, however, sometimes difficult of employment in young children, and then, under these circumstances, Dr. R. Liveing recommends that the skin he powdered with equal parts of oxide of zinc and starch, to which a few grains of powdered campbor are added. In some cases linscel-

^{*} Op. (0, c), 20;

I Fernada IIII:

B. Zinci cayd, Puls. rangli, 44 Puls. Camphers,

meal positions should be afterwards applied. When the cruption is very irritable, covering the parts affected with benzeuted zinc cintment and sleeping in an old lines shirt are advisable. The ang. plends applied on mg and kept on by a bandage is very serviceable; it was highly recommended by the late Dr. Tilbury Fox. Calamine and exide of sine form a good lotion in acute eczema.* In regard to constitutional remedies, aperients and alkalies may be required whilst the stage of excitement lasts. Later on, the mineral soids, with a litter, are serviceable (Form, 14-20). Amenic, too, with or without the vinum ferri, is useful (Form, 98).

Obvenie extens is sometimes a consequence of the armte variety. The skin is roughened and in a state of chronic inflammation, whilst at the bends of the joints there are cracks and fassares with silvery shining crusts upon them. The skin is very irritable and smarting; if the cruption be situated near the vulva or area, the itching is distressing, and patients cannot prevent scratching themselves when warm in bal at night. The disease any continue for months and years. I have seen a few obstinate cases in young children not exceeding seven years of ago, in whom the paternal parents, and their uncestors for two or three generations, were gonty, and some of them had suffered from exceens.

Treatures.—Coffee and stimulants should be proided, and the diet should be light and matritious. The lowels should be regulated by gentle aperients, and all sources of irritation, as worms, be removed. Arsenic alone, or in combination with iron, will be found most serviceable (Form, 36). Condition of the anti-extract, sto, may be given to weakly and stramous children. To remove the crusts which collect on the head they should be well moistened with oil, and then a poultice of bread and water applied afterwards, Later on the ung. hyd. cum plumbo, or diluted nitric oxide of mercury continent with creasone, will be beneficial.

Obstinate and chronic as this disease is, it is generally curable if a the treatment adopted be judicious, carried out regularly, and for a

			two Lab	527					

sufficient length of time. Each stage must be watched carefully, and the treatment varied according as it is inflammatory, resicular, or squamous ; in one stage the skin is too active, in the other it requires to be reased into activity and energy. Constitution, dyspensia, hepatic disorder, recal inadequacy, and general delicity, have all to be considered in carrying out the treatment.

Herpes, or tetter, consists of a cluster of globular vesicles situated on an inflamed loss, the contents of which soon change from a clear to a milky fluid, and then dry up, leaving a brown scale

Two kinds are generally described:

1. Herpes Inbialia.

2. Herpes zoster.

 Herpez labialis is usually seen in catarrh, and is pulmonary affections. It may last two or three weeks, and is unaffeeded with any constitional disorder.

Herper restor is almost unknown in infants at the breast. It
is care under five years of age. It is characterized by the vestelest
encircling one-half of the body, and being attended with intense
heat and itching. Severe neuralgia sometimes follows after the
eruption has healed.

The treatment consists in the use of mild aperients, warm batter, and plain diet. Lead lotion, and the ung. xinci beur, are both serviceable for the relief of pain and local irritation.

Effysion is a disease in which large pastules form situated on an inflanced portion of the skin. They break and dry into thick scales, and when they fall off there is utceration beneath. When this has bealed the neighboring skin is of a purplish tint. The disease is seen in strumous and body nourished children, and it is an occasional sequels of scariatina and mossles. The disease may be seate or election. The acute form of the affection is attended with slight febrile disturbance, headache, less of appetite, hoat, and itching. It may has two or three weeks. Tartar emetic similar produces a similar eruption. The phronic form is often seen in delicate infants and young children. There is no fever and no pain. The postules are very large, and successive crops may spring up, and continue for two or three months.

Treatment.—The scabs should be removed by poulticing, or moistening with warm oil. The olders should be dressed with lead lotion, or water-dressing if inflamed, and if indolent with the nitric oxide of merenry cintment, or some similar application. Good food, cod-liver oil, mild aperients, will be asseded. The mineral acids and back, the vinum ferri and arsenic (Form, 93), are also serviceable.

Legacion.—This disease is more common than that which has just been described (ectherna). In most cases these are forms of pustular eccena. The disease consists in the appearance of small pustules, which come to maturity in the course of a day or two. They then burst and discharge thick pus, which becomes transformed into a browish-yellow scab. Pus often continues to come from under the scab or crust, and when the scab finally separates, a red mark is left.

Impetigo may be seen on the arms, legs, face, or sculp. "When it attacks the face of children it is known as create better.""

The disease is generally due to debility, and is of frequent occurrence in children. Pediculi of the head by causing irritation may excite it.

Treatment.—The diet should be plain, simple, and nutritious, all stimulants being avoided. Aperients, followed by tonics, as quining, will be serviceable, and if the disease threatens to become chronic, indide of potassium with back will be necessary, and boths to improve the state of the skin. Locally, positions to remore crusts will be required, and the sores abould be dressed with dilute citrins ointment, or the white precipitate circument.

Lapus valyaris is a chronic discase of the skin, non-contagious, and, though common in early life, is rarely seen in children under two years of age (Liveing). It usually attacks the face, and more particularly the nose, but it may occur on any part of the body. It begins with small reddish tubercles, which increase is size, and then alcerate. The discase is associated with the strumous diathesis. It may be mistaken for syphilis, and in older persons it has been confounded with cancer.

Treatment.—This consists primarily in constitutional measures, fresh sir, snimal food, and a liberal diet, of which milk should form a chief part. In respect to medicines, condiver oil is most countial, and iron and arsenic are valuable remedies. The local treatment consists in the application of some caustic, as the acid sitrate of mercury.

Discours of the scolp may be thus arranged;

- 1. Alogecia areata, or tinea docalvans.
- 2. Tinea tonsurans, or common ringworm.

Alopeois areasts is a non-parasitic disease; it consists of an atrophied state of the roots of the hair, which terminates in haldness. The hair first becomes dry, and then it withers and falls off, leaving white and smooth circular patches. The most common site is the scalp.

As to the pathology of the affection, a fungus was formerly believed to be developed within the follicles of the roots of the hair, composed of small, round, and spores, which form into a layer at the roots of the hair, and then spread to the cattele. This view is

nour rejected by the most competent electrons.

Trestand.—This is very unsatisfactory; but painting the affeeted parts with tincture of todine once or twice a day, or occasionally blistering with the finid blister of the Pharmacoporia, often brings about a cure. Dr. Hillior recommended rubbing the bald parts with a liniment composed of equal parts of tincture of cantharides and clive oil. Strong carbolic acid is an excellent application.

2. There Teneurous (ringworm of the scalp).—In this disease the roots of the hair become mouldy, and at last break away near the surface of the skin. The hairs are leittle and thickened, readily breaking at the roots, which present a split and ragged appearance. Dry, scaly, and circular patches form, varying from half an inch to three or four inches in diameter. Vesicles are also sometimes seen, and a viscid fluid escapes from the follicles. This disease is contagious, and its origin depends on a fungus with real or rounded spores.

Treament. The tame as that recommended for the previous disease in an early stage. Later on, if it does not yield, a fairly strong citrine continent, night and moreoug, will core most cases. Carbolic acid, or the carbolized glycerin of the Pharmacopsia, are useful. But the affection is almost always tedious, and if a cure is effected in three months the treatment may be considered sat-

Esfactory.

Scalins, paors, or itch, is a disease arising from the scarus scaling (itch mite) harrowing beneath the cuticle, and there depositing its eggs. It may be seen in this situation as a small body, the skin presenting at the point of entrance a papular elevation. The spot asually seen is beneath the skin between the fingers and toes, at the bend of the chow, the axilla, and behind the knee; but it may attack any part of the body, especially in children. When the vesicle is broken, scales or crusts are formed. In these crusts young animals are contained. The irritation or scratching may occasion various forms of externs and articaria, according to Dr. Liveing, especially in long-standing cases in children.

To ansent.—The child should have a warm bath before going to bed, and be masked with soop and tlamed. After being well dried he should have the sulphur and potash ointment* rubbed into him. He should then be clothed with flannel, and wear gloves and socks, to prevent the application from rubbing off. The next night the process should be repeated, and it may be necessary to repeat it for a third night. A sulphur bath is also as excellent remody, and may obviate the use of the cintment altogether.

Philipson's - Loughess. - This disease arises from the being situated on the body. The most common sites are:

- 1. The head (Pedicular reports).
- 2. The body (Podiculus corporis).
- S. The publis (Policulus publis).

The eggs, which are known as nits, lite the skin, and produce a postular eruption and insufficially itching.

The tenturest, which is always effectual, consists in rubbing in mercurial ointment or the white precipitate continent. A few applications generally suffice for a cure. For Policeli carporis, staphisagra ointment (Squire's formula) is the best and safest.

COLUMN TO SERVICE AND ADDRESS OF THE PARTY O

These publications may be had through BookenBers in all the principal chies of the United States and Canada, or any book will be acut, postpaid, by the publisher, whom receipt of princ, in will be forwarded by express C. O. D. spon receiving a province of 25 per cent, of the amount someonic to these express charges.

MEIGS AND PEPPER, ON CHILDREN.

THE MOST THOROUGH, COMPLETE AND PRACTICAL WORK ON THE SUBJECT NOW BEFORE THE PROFESSION.

A PRACTICAL TREATISE ON THE DISEASES OF CHILD-

REN. By J. Forstern Mason, st.m., one of the Physicians to the Pennsylvania Hospital, Consoling Physician to the Children's Hospital, etc., and William Preven, st.m., Professor of Clinical Medicine, University of Pennsylvania, Provost and en officio Pensident of the Faculty, Physician to the Philadelphia Hospital, Fellow of the College of Physicians, etc., etc. The Seventh Rowland and Improved Edition. In one volume of over 1000 royal ectavo pages.

Price, handsomely bound in Cloth, \$5.00; Leather \$7.00.

The rapid sale of six large editions of Drs. Meigs and Pepper's work on Children, and the demand for the new edition now ready, is sufficient evidence of its great popularity. The large practice, of many years' standing, of the authors, importate its value anequaled, probably, by any other on the subject now before the profession.

The estire work has been now again subjected to an entire and thorough revision, some articles have been provinces, many additions made, and great care observed by the arthors, that it should be most effectually brought up to the light, pathological and thorapeutical, of the present day.

The publishers have very many favorable natices of the previous editions, received form numerous courses, foreign and daments. They append a few from leading journals, which will give a general idea of the value placed upon it, both as a Text Book for the Student and a work of reference for the General Proceditioner.

" It is the most complete work input the publics is not language, it does not done the results of personal and the temperature of efficient the quantum after the most reason authorizing both at these and about, are imple, and are should the authors describe programmations for his dog produced a bank accupated for the use of the emilienant independent or a work of reference for the programmate."—describes Abullian Neutral.

Fut as a transitio guide in the diagram's and treatment of the florance of children, we do not have to say that we have reliant over out a test book against them, so just, and as readable, in the own before to, which is in own in an account to to make therete whenever is small go, and whitever great studiests, provided year, and these and agreeable decreases appreciable."—of my studiests of Children in appreciable."—of my studiests of Children in a provided and agreeable of Children in a provided and agreeable of Children in a provided of the contract of Children in a provided of the contract of the

" It is only freely trees trees we had the pleasure of measurementing the Fifth Edition of this security work.

With the second address is may taken be performed out of the best and among temperature marks or discussed
of state of which the American Procedures was sould bissoid, for earliest reference."—If Y. Mod. Januari.

"It is not commonly to very more, in the erry of relations, of a such as well-known. The is a plantal. Like to some other good functions method is not related by not provided problems as extended of all the best flaminguage likewises are assumed, such artifacts throughout of good personal polyment, betweenings, and experience. The book this relation is experience of distriction as experience of districtions reportation of districtions. We are also be not below to such the next bloom of clinical windy, in the latest physiciagnal, parketingual, and therepoint all science."—Lamber Lawer.

Carrary, Member of the Imperial Academy of Medicine, Adjunct Professor in the Faculty of Medicine in Paris. Remodeled and rearranged, with revisions and additions, by S. Tausten. at D., Professor of Obvietnes and Diseases of Women and Children in the Faculty of Medicine of Paris. A New American, from the Eighth French and First. Italian Edition. Edited and Enlarged by Rosear J. Histo, u.p., Physician to the Northern Dispensary, Paris, etc. About 1100 pages quarto, with 12 Fall-page Plates (from of which are beautifully colored) and over 175 Wood Engravings.

Sold by aidscription only. Circulars and information will be sent, upon appliestion to the Pallithers.

For interp years "Channes's Ofinianics" has been use of the leading text-banks to America and England, to and as in France, and the second decision of fine of the Inventor Feedbaster of DaSy, Dec. Classes, Marriage, Parel. and There to provide a time their own tangenge, is a farther yound of its metalogic, and there is not more highers at a practical gaids to the general practitions. Another and perhaps a stronger good of the value of the great work, is the fact that by comparing unley of the heat-books issued since the first edition of Compac was pullished, it will be found that the laser authors have, to more or less passed, used it as a functions for dies mark, through case, conditions and discussions from his man of farm and the representation which Wat these impressed proofs to their send, the publishers depressed to large a new attack within with represent the advances much by the attence of materialsy. Wygon, expensive for the set of practitioning and endone of motions, and show of midwiley experiely, he teachings are plate and english presenting a ambiened summary of the hading principles established by the marries of the streets, are, and each time, processed from the the management of the progress, partnered and purposed years, as have been sampled by the most authorizate pragmining, and conformed by the author's contrapentate. The publishes referred for others a gendeman who had had an executed experience to primate practice and through his connection with me of the largest public depressions in the country. The sections has to some nation from based on the last French private, and on the revisions and additions much by the Indian resolution. The wivings of other wellhowever men have also been drawn from, as well so the experience of the adinor, an experience galend in everyany work. New chapters or sections have been existen, new illustrations innoted, ald game penut, and pusite tell-page places added; fine of which are rational.

HARRIS, THE PRACTICE OF DENTISTRY. Tenth Edition.

The Principles and Practice of Dentiny. Tenth Revend Edition. In great part Rewritter, Recurringed, and with many new and important Illustrations. By Chartes A. Hausers, S. D., Dents. Edited by P. H. Averras, M.D., Professor of Dental Science and Mechanism in the Bultimore College of Dental Surgery, With nearly 400 Exestrations. Royal Octaver, Price, Cloth, \$6.50; Leather, \$7.50.

This new edition of Dr. Harms work has been thoroughly revised in all its parts, more so than any previous edition. So great have been the advances in many branches of dentistry that it was found necessary to rewrite the articles or subjects, and this has been done in the most efficient manner by Professor Austra, for many years an associate and friend of Dr. Harms, assisted by Professor Gorgas and Thornas S. Latimer, w.o. The publishers feel assisted that it will now be found the most complete text-book for the scadent, and guide for the partitioner in the English language.

NOW READY.

Diseases of the Liver.

BY GEORGE HARLEY, M.D., F.R.S., Erc.,

Anthor of "The Union and In Decognition," and "Underen In Venior Front and Transmiss."

On Pine Paper, from Good Type, with Colored Plates and Thirty-us Wood-can-Sound in House Cloth, Breefed Edger, \$5,00; Leather, with Rained Benth, \$2,00.

THE Publishers call special attention to this work, the only thorough book most before the profession. The reputation of its distinguished author is a gravannee of its marins.

THE AUTHOR, IN MIS PREFACE, SAYS.

THIS NEW TREATISE, which I have thought fit in entitle Doctors of the Liver, with and without Jaminice, with special application to Diagrams and Trestment, embodies within it the whole substance of my original managraph on Jameire and Diseases of the Liver; though greater then it, both at negatid in scope and ensternals, and the large amount of cliencal and eccentric dum that has never before been collected tigether into one volume; while in a great many instancesit gives a new rendering to all clinical facts, by presenting them to the reader in

the light of modern pathological amenor.

As I think time is quite of an much value to the professional as it is to the correantle man-I have endeavored to condense my materials to the amout, withour rurning the risk of endangering their perspiciety. Added to which, in this treatme has not been permed either for the use of the tito or the dilettime in modified but for that of my qualified heethers, I shall reither waste nine by entering imp detailed accounts of the literature, not give todious, and probably in the same zinc profitlitis, discussions of the theories of the erechanors of justiskie in hepatic derangements. Taking care, however, in order that it may easily more wright with it in the eyes of the reader, to illustrate a freely with cases reported by independ dent observers, both at home and abroad. While, in order, again, that the seather may be able to see for himself, at a glance, how many of the old-trab med theories of the pathology of painting have been shirt-level, as well as how many new over have been approved. I have pot my views, in accordance with the facts and arguments expressed throughout the budy of the volume, little a contine and Cognamicatic tateries forms

I WOULD DIRECT the special amounts of try renders to the chapter deroted to creatment, as well as that as the and of one book, entitled it into on Disgressin.
